Last year the contributory scheme of the Radcliffe Infirmary, Oxford, produced £36,778, the largest sum yet received, an increase of £2000. Of the 4752 in-patients 61 per cent., and of the 10,694 out-patients 71 per cent., were members of the scheme.—The workmen's hospital fund of the Royal Gwent Hospital, Newport (Mon), last year amounted to £12,400, out of a total income of £28,000. There was a small surplus.—The industrial situation was responsible for a fall of £1183 in workmen's contributions to the Palmer Memorial Home at Jarrow.—The contributory scheme of the Royal Buckinghamshire Hospital, Aylesbury, has shown continuous increases from £2954 in 1926 to £4456 last year, when the total expenditure of the institution was £11,904.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 16TH, 1932.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 87 (last week 73); scarlet fever, 1512; diphtheria, 716; enteric fever, 20; acute pneumonia (primary or influenzal), 1036; puerperal fever, 37; polio-myelitis, 113; cerebro-spinal fever, 78; acute poliomyelitis, 10; encephalitis lethargica, 11; continued fever, 1; dysentery, 31; ophthalmia neonatorum, 97. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on April 19th–20th was as follows: Small-pox, 122 under treatment, 1 under observation (last week 117 and 6 respectively); scarlet fever, 1406; diphtheria, 1369; enteric fever, 11; measles, 2696; whooping-cough, 423; puerperal fever, 25 (plus 14 babies); encephalitis lethargica, 226; poliomyelitis, 5; "other diseases," 112. At St. Margaret's Hospital there were 13 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was 1 death from small-pox, 1 (1) from enteric fever, 132 (61) from measles, 9 (1) from scarlet fever, 42 (6) from whooping-cough, 29 (4) from diphtheria, 57 (16) from diarrhœa and enteritis under two years, and 85 (16) from influenza. The figures in parentheses are those for London itself.

The fatal case provisionally classified to small-pox occurred in Camberwell Metropolitan Borough. No great town reported more than 3 deaths from influenza. Liverpool reported 16 deaths from measles, Leeds 7, Manchester 5. Whooping-cough accounted for 8 deaths at Liverpool, 5 at Birmingham.

The number of stillbirths notified during the week was 276 (corresponding to a rate of 38 per 1000 births), including 42 in London.

FATAL CASE OF SMALL-POX.—This case which occurred in Camberwell was, Dr. H. W. Barnes tells us, that of a woman, aged 79 years, whose death on April 10th was certificated as due to (1a) cardiac failure, (b) senility, (c) variola. There was no post-mortem examination.

Appointments

BAILEY, H., F.R.C.S. Eng., has been appointed Consulting Surgeon, Essex County Council.

Certifying Surgeons under the Factory [illegible]
COCK, G., L.R.C.P. Lond., M.R.C.S [illegible]
HUMBLE, J. W. M., M.B., Ch.B. G [illegible]
KINGDON, M. C. H., L.R.C.P. Lond., [illegible]
Devon); STRACHAN, F. J., M.B., B. [illegible]
WORTHINGTON, C. L., M.B., B.S. Lond. (Leamington, Warwick).

OBITUARY

SIR WILLIAM WATSON CHEYNE, F.R.C.S., F.R.S.,

LATE PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

WE announced last week the death of Sir Watson Cheyne, which occurred on Tuesday, April 19th, in his eightieth year.

William Watson Cheyne was born in 1852, the son of a Scottish clergyman, Andrew Cheyne, of Fetlar, Shetland. He was educated at the University of Edinburgh and graduated in the medical school with first class honours as M.B., C.M. in 1875. He was a distinguished student, securing various prizes, and after graduation pursued his studies in Vienna and at the University of Strasbourg. He marked himself out, even in student days, for Lister's devoted follower, as the following passage quoted from the first Lister Memorial Lecture, which was delivered by Cheyne before the Royal College of Surgeons of England in 1925, shows vividly. He said:

WATSON CHEYNE.

[*Photograph by Elliott & Fry.*

> "I shall never forget the first day that I went to the hospital (Royal Infirmary, Edinburgh). At 12 o'clock I . . . found crowds of students hurrying along the lobbies, a good many, indeed, running. I joined the company, full of curiosity, and found that we were going to Lister's clinical lecture. We ultimately reached the large operating theatre and found it filled with men crowding the gallery and standing at the back and in the gangways: there must have been over 200 there, and they were senior men, for the clinical surgery class was not usually attended till the fourth year. I should think that I was the only one of my year there. Presently a man walked into the arena, sat down in a chair placed on the floor of the theatre; crossing his legs and putting his right hand on his thigh, he began his lecture. This man was Lister. He had not spoken many minutes before I became fascinated with the subject and could not help seeing the wonderful era that was dawning for surgery. I had my notebooks for my other classes in my hand and I started to take down what he said, and, as he spoke very slowly and clearly and I scribbled very quickly, I was able to take down practically the whole lecture, though, not having learnt any surgery, I did not understand it at all clearly at first. But what a contrast with the lectures on systematic surgery ! . . . Is it any wonder that I left the theatre an enthusiast for the profession that I had chosen, and that on lecture days I was one of those who ran."

On his return from the continent Cheyne became Lister's house surgeon and right-hand man in the development of antiseptic surgery nearly from its birth. In 1877 he was elected to the Syme Surgical Fellowship, and became demonstrator of anatomy in the University of Edinburgh. But in that year Lister was invited to join the staff of King's College Hospital, with a chair in surgery at the institution specially created for him. This was the official recognition in London of the fundamental value of Lister's discoveries, and it was not forthcoming without opposition, sometimes of a vexatious sort. Lister, however, was able to make a stipulation which showed the unusual nature of the appointment, and was allowed to bring with him from Edinburgh four men as his assistants, who had been thoroughly trained in the new methods: of these the principal was Watson Cheyne, who now became his house surgeon, the others being John Stewart, senior assistant, and W. H. Dobie and James Altham, dressers, the last two being still unqualified. The story of the early stages of Lister's work at King's College makes painful reading, and Cheyne, at first, shared in his leader's chilling reception. John Stewart has recorded the feelings of the four expatriated Scots in feeling words:

> "The next few weeks were to us of his (Lister's) staff the abomination of desolation. There seemed to be a colossal apathy, and inconceivable indifference to the light, which, to our minds, shone so brightly, a monstrous inertia to the force of new ideas. We four unhappy men wandered about now in the wards of King's, now through older and more famous hospitals, and wondered why men did not open their eyes. In these wards the air was heavy with the odour of suppuration, the shining eye and flushed cheek spoke eloquently of surgical fever. We would show them how things should be done. But how ? We had no patients. We thought of the crowded hours of glorious work in Edinburgh, where Lister had half a dozen wards and 60 or 70 patients, and groaned over our two wards with capacity for a couple of dozen, but only empty beds."

The fact that owing to the lukewarm support of the staff and the apathy of the students the wards under Cheyne's charge were often more than half empty had, however, one distinctly favourable impression upon his career, for he found time to study for the English fellowship and made good use of his opportunities. In 1878 he was made additional surgical registrar to the hospital, in 1879 he took the F.R.C.S. diploma, and in 1881 he secured the Jacksonian prize with an historical epitome of the principles, practice, history, and results of antiseptic surgery; and in the same year he was elected assistant surgeon to King's College Hospital. The association with Lister secured him no quick private practice, but the post-operative care of Lister's cases remained usually in Cheyne's hands. The time soon came when Lister had patients sent to him from all parts of the world, while his advice was regularly sought by consultant physicians at home. In a large proportion of his operations he was accompanied by Cheyne, or by his other great lieutenant (and nephew) Rickman Godlee, and Sir Lenthal Cheatle, who worked as junior with both Lister and Cheyne in private practice, has put it on record that the younger man's accurate judgment and sound sense were made free use of by his chief. At length Cheyne's private practice became a very important one, but for some time the public, and his colleagues, regarded him persistently as a bacteriological assistant to Lister. By his own hospital work, however, he proved himself a thoroughly sound and skilful operator, and as a teacher was in his element; his lectures were among the first, possibly the first in this country, to be illustrated by lantern slides. Cheyne was also responsible for a great advance in clinical teaching at his hospital. Appointed demonstrator or surgical pathology at the hospital, he secured the methodical microscopic examination of all tissues removed at operations, and he incorporated the results of these investigations into the histories of the cases. To carry out this scheme thoroughly he inaugurated a department of his own at King's College Hospital, and paid himself for the establishment of what was really an institute of clinical pathology. Sir Lenthal was his assistant in those days, and records not only his personal debt to Cheyne as an instructor but the advance in scientific teaching that was inherent in making of clinical pathology a hospital department. Cheyne's investigations into tuberculosis and his extensive morphological examination of tuberculous lesions confirmed Koch's discoveries in that field and were models of such work, and his early election to the Royal Society followed. He was, as might be expected, a model examiner, though more lenient than his reserved manner suggested; but no candidate had reason to feel that he had been deprived of chances of making good, and as an examiner he assisted the Universities of Edinburgh, Oxford, Cambridge, and London.

When the South African War broke out Cheyne was immediately appointed civil consulting surgeon to the forces; he obtained mention in despatches and received the C.B. for valuable services. During the fifteen years which elapsed between the end of this struggle and the breaking out of the European War, he was one of the recognised leaders of the surgical profession in the country, filling almost every high office that was open to him. In 1908 he received a baronetcy, and was appointed Surgeon in Ordinary to the King. His association with the Royal College of Surgeons of England had always been intimate. He had not only gained the important prizes but had been Hunterian Professor, and for many years was on the Council. In 1914 he was elected President, and during his term of office the European War broke out. He was appointed consulting surgeon to the navy with the rank of Surgeon Rear-Admiral, and most of his service was discharged in England at Chatham. The appalling experience of our troops from septic wounds drew from him certain communications which placed him in opposition to the views held by other authorities, and he became involved in a polemical discussion which, personalities apart, had its prototype in medical literature some ten years previously, when questions of "sepsis" as against "antisepsis" were hotly debated. Cheyne resented the personal note of some of the reflections upon his views, but looking back on the matter it must be admitted that he had courted criticism, being probably influenced in some of what he said by a too great respect for unessential parts of Lister's original teaching. He was quite a good controversialist, but the double nature of his duties as President of the College of Surgeons and consulting surgeon to the Navy were trying him considerably at the time, and no one regretted that he withdrew from the discussion.

In 1916 Cheyne was made a K.C.M.G., and in that year his term of office as President came to an end. He retired almost immediately from practice, when he was elected to represent the conjoint Universities of Edinburgh and St. Andrews in Parliament. In the House of Commons he proved a real success; he spoke with authority and without dogmatism on what he knew, and only when his particular knowledge was likely to be of service to the Members. In 1918, under a new combination of Parliamentary seats, Cheyne became M.P. for the Combined Scottish Universities, and came to live near London so as to be able to attend to his Parliamentary duties. But his health was already undermined and about ten years ago he retired to his Scottish home, in the Shetlands, and was gazetted Lord-Lieutenant of Orkney and Shetland.

Cheyne was a clear and practical writer, his teaching being always founded on his experience. As far back as 1882 he wrote the Principles, Practice, History, and Results of Antiseptic Surgery, this being an expansion of the Astley Cooper prize essay. This work would repay consultation to-day. In it Cheyne marshalled the facts which made good the position of antiseptic surgery, and stated the case so completely that his words, which were sometimes disrespectful to the older school, became the starting point for the general acceptation of the new view. Three years later he wrote a manual on the antiseptic treatment of wounds, and later still he published lectures on suppuration and septic disease, on tuberculous disease of bones and joints; and, lastly, in coöperation with the late Mr. F. F. Burghard, his great Manual of Surgical Treatment.

We owe to Sir Harold Stiles the following appreciation of Sir Watson Cheyne:—

"I had the good fortune to get to know Cheyne about 40 years ago, when he was the extra-examiner in surgery in the University of Edinburgh. I was in charge, under the late Prof. Chiene, of the department of surgical pathology, and I well remember how keenly interested Cheyne was in my demonstration to him of cancer cells in the efferent lymphatic vessels in and around the mamma in carcinoma of that organ. It was largely due to Cheyne that my researches on the dissemination of cancer were brought to the notice of surgeons in support of the radical operations now generally adopted. At the time of which I speak Cheyne was carrying on his classical researches on tuberculous diseases of the bones and joints, for which he was awarded the Astley Cooper prize, and our keen interest in surgical pathology created a bond between us which ripened into a lifelong friendship. His house in Harley-street was always open to me, and I shall never cease to be grateful to him for his help and encouragement during my struggling days, and above all for his example and inspiring influence. I had the same admiration and reverence for him that Lister's pupils had for their great master.

"Although in his early days Cheyne made a great reputation as a pioneer in surgical bacteriology he had a hard struggle to make both ends meet—indeed, he told me that if he had failed to gain the valuable Astley Cooper prize he might have had to go into general practice. He keenly resented the slowness with which operative work came to him, for he had good reason to think that he was generally spoken of as a bacteriologist and pathologist rather than as a surgeon. I remember his indignation when he was asked by the editor of a large work to write the article on pyæmia: he replied effectively that while he had often produced the disease experimentally in animals he had had no experience of it in the human subject. As was only to be expected, Cheyne was the last of the diehards to abandon antiseptics for a strictly aseptic technique. It was in 1893, after working under Kocher, that I introduced the technique at Edinburgh, when Cheyne paid a visit to the Edinburgh Hospital for Sick Children to see the details carried out. That he was not convinced of the superiority of the aseptic methods was evident from the fact that shortly afterwards he chose as his subject for a Bradshaw lecture 'The advantages of towels soaked in 1:20 carbolic acid over dry sterilised sheets.' I think he was alarmed at seeing me place instruments on a dry sterilised sheet instead ed into a 1:20 solution of carbolic acid. He was evidently still afraid of the germs in the atmosphere. It is only fair, however, to say that Cheyne got better results by his antiseptic methods than did many surgeons who professed to carry out an aseptic technique, while I think that ultimately he became a convert, and that the removal of his handsome beard was an outward and visible sign of that conversion.

"Cheyne was a true man of science as well as a great clinician, and as an operator was superior to his great master. In my earlier days I took him as my pattern of an ideal surgeon. I was fascinated, not so much by his dexterity and rapidity, but more particularly by his calmness when in a tight corner, and above all by the thoroughness, which was seen at its best in his operations for tuberculous or malignant conditions. He had the confidence, born of real knowledge, but he was as modest about his work and capabilities as he was quiet and unassuming in his manner. For years he was one of the busiest of men; and while he shouldered a heavy burden of responsibility and got through a prodigious amount of work, he never seemed to be in a hurry.

"Cheyne had a warm heart and a tender nature, which he hid deliberately or from a sort of innate shyness. He could not suffer fools but none could wish for a truer or stauncher friend, and few men who have reached the high position to which he attained were more deservedly trusted and honoured. To his intimate friends he did not hesitate to reveal the very human side of his character, and he was seen at his best when on holiday at his island home in Shetland where he was greatly beloved; lucky were those who were privileged to be his guests, and they were many. The consummate skill with which he handled his sailing boat in a dangerous sea convinced us that he had the blood of a Norse Viking in his veins."

Many of Cheyne's honours have been already mentioned, but their list is not exhausted. He received honorary doctorates from the Universities of Edinburgh and Oxford, and honorary diplomas from the Scottish corporations, and many prizes from other bodies. His last distinction of this sort was appropriate indeed, when he became in 1924 Lister Memorial Medallist and Prizeman. It was fitting that Cheyne's concluding literary work should have been the expansion of his prize address into that fascinating little book, "Lister and his Achievements."

Sir Watson Cheyne married, first, in 1887, Mary, daughter of Mr. William Servanté, of Plumstead, and, secondly, Margaret, daughter of Mr. George Smith, of Lewick. He is succeeded in the baronetcy by his son, Lieut.-Colonel Joseph Lister Cheyne.

Dr. **ARTHUR EDWARD SPROULLE**, who died at Rotherfield, Sussex, on April 18th, came of a family of doctors. He was born at Mourveen, near Londonderry, in 1866, the son of Dr. Thomas Sproulle, and his four brothers were all medical men. Qualifying L.R.C.P. & S.I. at Dublin in 1889, he settled at Withernsea, Yorks, then little more than a fishing village, in 1892, and for 38 years carried on practice there, watching it grow into a prosperous seaside resort of 5000 inhabitants. When the village became an urban district in 1898, he was appointed medical officer of health, a post he held until his retirement on account of ill-health in 1930. For a large part of the time he was the only doctor in the town, and there is no doubt that continuous overwork, particularly during the war years, when he also looked after large numbers of troops, laid the foundations of the illness which caused his death at a comparatively early age. He was a sound and careful physician, and the respect in which he was held by his professional brethren was shown by his election as chairman of the East Yorks Division of the B.M.A., and later, of the East Yorks and North Lincs Branch. He took a keen interest in the welfare of his township and at one time no meeting in the town was complete without his presence. He raised and trained a division of the St. John's Ambulance Association, was local agent for the Shipwrecked Mariners Association, and a member of the crew of the Withernsea lifeboat, rowing in the boat to a number of shipwrecks.

Medical Diary

SOCIETIES.

ROYAL SOCIETY OF MEDICINE.

TUESDAY, May 3rd.—5.30 P.M., ORTHOPÆDICS. (Cases at 4.30 P.M.) Mr. H. A. T. Fairbank: 1. Dupuytren's Contraction of the Plantar Fascia. Mr. E. Laming Evans: 2. Multiple Fatty Herniæ in Feet. Mr. C. Lambrinudi: 3. Bad Posture Due to Short Hamstrings. Mr. Eric I. Lloyd: 4. Syphilitic Epiphysitis of Upper End of Femur. Other cases will be shown. 7.45 P.M., DERMATOLOGY. Annual Dinner at Langham Hotel.

WEDNESDAY.—5 P.M., HISTORY OF MEDICINE. Paper: Dr. Harley Williams: The Growth of our State Medical Services. A discussion will follow to be opened by Sir Weldon Dalrymple-Champneys. EPIDEMIOLOGY AND STATE MEDICINE. Members of this Section are specially invited to attend and to take part in the discussion. 6 P.M., SURGERY.

THURSDAY.—8 P.M., TROPICAL DISEASES AND PARASITOLOGY. Paper: Colonel S. P. James: A Study of Induced Malignant tertian Malaria. MEDICINE: THERAPEUTICS AND PHARMACOLOGY. Members of the Sections of Medicine, Therapeutics, and Pharmacology are specially invited to attend.

FRIDAY.—10.30 A.M., OTOLOGY. (Cases at 9.30 A.M.) Papers: Dr. Logan Turner and Mr. J. S. Fraser: Labyrinthitis: Treatment and Results. Mr. J. S. Fraser: A Case of Bilateral Labyrinthitis. (With slides.) A discussion will follow to be opened by Mr. Sydney Scott. Other speakers: Mr. W. Mollison, Dr. Dan McKenzie, and Mr. F. W. Watkyn-Thomas. 5 P.M., LARYNGOLOGY. (Cases at 4 P.M.) Clinical Meeting. 8.30 P.M., ANÆSTHETICS. Dr. H. Bellamy Gardner: Aeris, The New Name Suggested for Nitrous Oxide and Oxygen. Clinical Meeting.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

WEDNESDAY, May 4th.—7.30 P.M. (at the Hotel Rembrandt), Excessive Surgery. Discussion to be opened by Mr. Zachary Cope, Dr. Geoffrey Evans, and Mr. Hamblen Thomas.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.

TUESDAY, May 3rd and following THURSDAY.—5 P.M., Dr. Harriette Chick: Relation of Light to Nutrition. (Oliver-Sharpey lectures.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, May 2nd, to SATURDAY, May 7th.—LONDON LIGHT AND ELECTRICAL CLINIC, Ranelagh-road, S.W. An evening course in Physical Medicine, Mon. and Wed., 8 to 9 P.M. Lectures and demonstrations on cases.—ROYAL ALBERT DOCK HOSPITAL, Greenwich, S.E. A week-end course of demonstrations on cases on Sat. and Sun., 9.30 A.M. to 6.15 P.M. (specially suitable for F.R.C.S. candidates).—INFANTS' HOSPITAL, Vincent-square, S.W. Afternoon course in Diseases of Infants.—MAUDSLEY HOSPITAL, Denmark-hill, S.E. Lecture-demonstrations on Psychological Medicine, afternoons only.—LONDON LOCK HOSPITAL, Dean-street, W. Afternoon and evening course in Venereal Disease.—CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C. All-day Clinical course in Diseases of the Ear, Nose, and Throat.—CHILDREN'S HEART HOSPITAL, West Wickham, Kent. Lecture-demonstration on Rheumatic Infection and Heart Diseases in Children. 10.30 to 12 noon, Sat., by Dr. Bernard Schlesinger.—ST. JOHN'S HOSPITAL, Leicester-square, W.C. Afternoon course of demonstrations and lectures on Diseases of the Skin.—(The above courses are open only to Members of the Fellowship.)

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith-road, W.6.

MONDAY, May 2nd.—10 A.M. to 1 P.M., Gynæcological Ward, Surgical Wards. Genito-Urinary Operations, Skin Department. 2 to 4 P.M., Operations, Surgical Wards. Medical, Surgical, Gynæcological, and Eye Out-patients. 4.15 P.M. (Lecture), Dr. Burnford: Febrile States and their Diagnosis.

TUESDAY.—10 A.M. to 1 P.M., Medical Wards, Surgical Demonstration, Throat Operations, Dental Department. 2 to 4 P.M., Operations, Medical, Surgical and Throat Out-patients. 4.15 P.M. (Lecture), Dr. Pritchard: Some Points in the Diagnosis and Treatment of Goitre.

WEDNESDAY.—10 A.M. to 1 P.M., Medical Wards, Children's Medical Out-patients. 2 to 4 P.M., Gynæcological Operations, Medical, Surgical, and Eye Out-patients. 4.45 P.M., Venereal Diseases Demonstration. 4.15 P.M., (Lecture), Dr. Burnford: Febrile States and their Diagnosis.

THURSDAY.—10 A.M. to 1 P.M., Neurological Out-patients, Fracture Demonstration. 2 to 4 P.M., Operations, Medical, Surgical, Genito-Urinary, and Eye Out-patients. 4.15 P.M. (Lecture), Dr. Burnford: Febrile States and their Diagnosis.

FRIDAY.—10 A.M. to 1 P.M., Medical Wards, Skin Out-patients, Dental Department. 12 noon, Medical Lecture. 2 to 4 P.M., Operations, Medical, Surgical, and Throat Out-patients.

SATURDAY.—9 A.M. to 1 P.M., Throat Operations, Medical and Surgical Wards, Surgical and Children's Medical Out-patients. The lectures at 4.15 P.M. on Mondays, Tuesdays, Thursdays, and Fridays are open to all medical practitioners without fee.

ST. PAUL'S HOSPITAL, Endell-street, W.C.

WEDNESDAY, May 4th.—4.30 P.M., Mr. Kenneth Walker: Alternatives to Prostatectomy in Prostatic Obstruction.

ST. MARK'S HOSPITAL, City-road, W.C.

THURSDAY, May 5th.—4.30 P.M., Dr. N. P. Henderson: Diagnosis of Carcinoma of the Large Bowel by X Rays and Opaque Enema.

ST. PETER'S HOSPITAL, Henrietta-street, Covent Garden, W.C.

WEDNESDAY, May 4th.—3 P.M., Mr. J. G. Sandrey: Post-operative Treatment of Prostatectomy.

LONDON JEWISH HOSPITAL, Stepney Green, E.

THURSDAY, May 5th.—4.15 P.M., Mr. Arnold Sorsby: History of Medicine.

SALFORD ROYAL HOSPITAL.

THURSDAY, May 5th.—Mr. R. Ollerenshaw: Demonstration of Orthopædic Cases.

NATIONAL CENTRE AND POST-GRADUATE SCHOOL OF RADIOTHERAPY, Riding House-street, W.

WEDNESDAY, May 4th.—4.30 P.M., Mr. S. Cade: Tongue.

UNIVERSITY COLLEGE, Gower-street, W.C.

MONDAY, May 2nd, and following THURSDAY and FRIDAY.—5.15 P.M., Prof. Otto Grosser: Human Comparative Placentation. (Lantern Illustrations.)

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.

MONDAY, May 2nd.—8 P.M., Prof. J. C. Drummond: Recent Researches on the Nature and Function of Vitamins. (Last of three lectures.)

UNIVERSITY OF BIRMINGHAM.

WEDNESDAY, May 4th.—4 P.M., Mr. C. J. Bond: Some Aspects of Human Biology. (Third of five William Withering memorial lectures.)

THURSDAY.—4 P.M., Prof. Seymour Barling: Operative Treatment of Toxic Goitre. (Ingleby lectures.)

MANCHESTER ROYAL INFIRMARY.

TUESDAY, May 3rd.—4.15 P.M., Dr. F. E. Tylecote: Hypnotics.

FRIDAY.—4.15 P.M., Dr. Crighton Bramwell: Demonstration of Electrocardiographic Methods.

ROYAL HOSPITAL FOR SICK CHILDREN, Glasgow.

WEDNESDAY, May 4th.—4.15 P.M., Dr. Stanley Graham: Medical Cases.

Vacancies

For further information refer to the advertisement columns.

[illegible] Hon. Asst. P.

—Jun., H.S. At rate of £120.

msdale Hospital.—H.S. At rate of

Bedford County Hospital.—Second H.S. At rate of £140.

Birmingham City, Maternity and Child Welfare Dept.—Four Temporary M.O.'s. £9 10*s.* per week.

Birmingham and Midland Eye Hospital, Church-street.—Two Out-patient Officers. Each 1 guinea per session.

Birmingham, Queen's Hospital.—H.S. At rate of £70.

Bradford Children's Hospital.—H.S. £100.

Bradford Royal Infirmary.—H.P. and H.S. Each at rate of £135.

Brighton, Royal Alexandra Hospital for Sick Children.—H.S. £100.

Burton-on-Trent, General Hospital.—Cas. O. and H.P. £150.

Cambridge, Papworth Village Settlement.—Second Asst. M.O. £400.

Canterbury, Kent County Mental Hospital, Chatham.—Jun. Asst. M.O. £350.

Carlisle, Cumberland Infirmary.—Res. M.O. At rate of £155.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Hon. Assts. for Out-patient Dept. Also Res. H.S. At rate of £75.

Chester Royal Infirmary.—H.P. £150.

Connaught Hospital, Walthamstow, E.—Res. Cas. O. At rate of £100. Also Hon. Anæsthetist.

Constance-road Institution, Dulwich, S.E.—Asst. M.O. £250.

Dundee Royal Infirmary.—Visiting M.O. for Diseases of the Skin.

Essex C.C.—Jun. Asst. County M.O.H. £500.

Evelina Hospital Hospital for Sick Children, Southwark, S.E.—Hon. Ph

Hospital for *Chest, Brompton, S.W.*—J At rate of £100.

Hospital for Sick Children, Great Ormond-street, W.C.—Secretary. £750.

Ipswich, East Suffolk and Ipswich Hospital.—H.S. £120.

L.C.C. Mental Hospital Service.—Asst. M.O. £475.

Leeds General Infirmary.—Hon. Asst. Physician.

Leicester, Combined Sanatorium and Fever Hospital, Markfield.—Med. Supt. £850.

Leicester Royal Infirmary.—Res. Asst. Anæsthetist. At rate of £250.

Lincoln County Hospital.—Jun. H.S. At rate of £150.

Liverpool, Alder Hey Children's Hospital.—Med. Supt. £1000.

Liverpool City.—Pathologist. £700.

Liverpool Sanatorium, Delamere Forest, Frodsham.—Asst. to Med. Supt. £250.

London Female Lock Hospital, 283, Harrow-road.—Asst. Non-Resident Surg. Reg. £50.

London Jewish Hospital, Stepney Green, E.—Res. M.O. and Cas. O. Each at rate of £150. Jun. Res M.O. At rate of £100. Also Clin. Asst. for Actinotherapeutic Dept.

Lowestoft, St. Luke's Hospital.—Res. Asst. M.O. £350.

Manchester, Ancoats Hospital.—H.P. At rate of £100.

Manchester, Royal Manchester Children's Hospital, Pendlebury.—Res. Surg. O. At rate of £125.

Maidstone, Kent County Ophthalmic and Aural Hospital.—Ophth. H.S. At rate of £200.

Middlesbrough, Holgate Municipal Hospital.—Res. H.P. At rate of £170.

National Hospital for Diseases of the Nervous System, Queen-square, W.C.—Res. M.O. £200.

National Temperance Hospital, Hampstead-road, N.W.—Hon. Asst. Phys.

Newcastle General Hospital, Newcastle-upon-Tyne.—Res. Med. Asst. At rate of £100.

Newcastle-upon-Tyne Hospital for Sick Children.—Jun. H.S. At rate of £100.

Plymouth, South Devon and East Cornwall Hospital.—Res., Anæsthetist and H.S. to Spec. Depts. At rate of £100.

Preston and County of Lancaster Royal Infirmary.—Cas. O. At rate of £150.

Princess Beatrice Hospital, Richmond-road, S.W.—Hon. Clin. Assts.

Royal Chest Hospital, City-road, E.C.—Res. M.O. and H.P. At rate of £150 and £100 respectively.

Royal National Orthopædic Hospital.—H.S. for Country Branch, at Stanmore. At rate of £150.

Ryde, Isle of Wight County Hospital.—Res. H.S. £180.

Salvation Army, Mothers' Hospital, Lower Clapton-road, E.—Sen. Res. M.O. £150.

Sheffield Royal Hospital.—Two Asst. Cas. O.'s. Also Res. Anæsthetist. Each at rate of £80.

St. Alfege's Hospital, Vanbrugh-hill, S.E.—Asst. M.O. £350.

Torquay, Torbay Hospital.—H.S. £175.

Weir Hospital, Grove-road, Balham.—*S.W.*—Jun. Res. M.O. for War Memorial Maternity Home. £150.

West Hartlepool, Howbeck Infirmary.—Visiting Consultant for Eye, Ear, and Throat.

Weston-super-Mare General Hospital.—Res. H.S. £150.

Winchester, Royal Hampshire County Hospital.—Res. Surg. O. Also Matron. Each at rate of £200.

Worcester County and City Mental Hospital, Powick.—Jun. Asst. M.O. £350.

The Chief Inspector of Factories announces the vacant appointments for Certifying Factory Surgeons at Uffculm (Devonshire) and Wartle (Aberdeenshire).

Workmen's Compensation Act (Northern Ireland), 1927. Medical Referee for the County and City of Londonderry. Particulars from the Secretary, Ministry of Labour, Stormont, to whom all applications should be forwarded not later than May 7th.

Births, Marriages, and Deaths

BIRTHS.

MCOUAT.—On April 18th, at the Private Hospital, Leicester, the wife of J. T. McOuat, M.B., F.R.C.S.E., of a son.

REED.—On April 21st, at High-street, Broadstairs, the wife of J. B. Reed, L.D.S. R.C.S., of a daughter.

MARRIAGES.

NORTHFIELD—SLATER.—On April 16th, at St. Mary's Church, Hendon, Douglas William Claridge Northfield, M.S., F.R.C.S., to Eva Marjorie, elder daughter of the late Mr. P. M. Slater and Mr

SUTHERLAND—CARTER.— Presbyterian Church, Bath, Al Ch.B. Edin., W. Leonard eld-gardens,

WILSON—SMITH.—On April 23rd, at All Saints' Church, Woodford Green, William Craig Wilson, B.A., M.B., Ch.B., and Edith Mary Partington Smith, M.A., B.Ch., only daughter of Mr. and Mrs. Harry Smith, Ryecroft, Woodford Green, Essex.

DEATHS.

CHEYNE.—On April 19th, in a nursing home, Sir William Watson Cheyne, Bt., of Leagarth Fetlar, Shetland, in his 80th year.

GIRVAN.—On April 17th, suddenly at sea, on board the s.s. *Duchess of York*, Alexander Girvan, M.D., F.R.C.S.Edin., of Brooke-road West, Waterloo, Liverpool.

SARJEANT.—On April 24th, suddenly, at Parkhurst-road, Holloway, N., John Frederic Sarjeant, M.R.C.S., L.R.C.P.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

THE CONTROL OF INDUSTRIAL RHEUMATISM.*

BY W. S. C. COPEMAN, M.B., M.R.C.P.,
S. PHYSICIAN TO THE BRITISH RED CROSS SOCIETY'S CLINIC
OR RHEUMATISM; ASSISTANT PHYSICIAN TO THE HOSPITAL
OF ST. JOHN AND ST. ELIZABETH, LONDON.

The Present Position.

1. *Medical aspect.*—A medical officer of health ently wrote: "One finds in institutions and ewhere a considerable number of persons incapaci-ted by rheumatic disease. The only medical sistance most can get is occasional drug treatment om town doctors or sporadic out-patient treat-ent. . . . These hopeless wrecks are considered evitable. (cf. position of tuberculosis 50 years o.)"

The insurance practitioner to-day has no power pass on rheumatic patients for special—e.g., ysical—treatment; and although this is true of ost diseases he would probably be specially glad do so in such a chronic disorder as rheumatism. l that he can do for the average case is to prescribe algesic drugs, give certificates for repeated absences om work, or advise his patient to go to hospital. his private capacity he may, in addition, diagnose e case correctly, give advice on diet, rest, exercise, plication of heat, or rubbing (by district nurse ssibly). give vaccine or shock therapy, and, finally, force of personality encourage the patient to rsevere. As regards perseverance, the lack of ficial liaison between panel and hospital often oves disastrous in any form of chronic disease, d this is particularly true of arthritis—although is would prove less important if beds and proper t-patient physical departments were provided sewhere. Under "dental benefit" focal sepsis om teeth is also dealt with.

The difficulties encountered in this field of medicine e great. This is. however. no good reason for ntinuing to ignore them. It seems reasonable to elegate them to those members of the profession ho wish to tackle them and recognise both medical d lay specialisation in this field as legitimate and esirable, as in the case of tuberculosis. The only urely medical body apparently attempting to deal ith the problem on a large scale at present is the igue internationale contre le rheumatisme, which as unfortunately no very active English committee. his body emphasises the need for, and fosters, aison between the medical profession, the State epartments, and insurance bodies in their common ttack on the problem.

The Ministry of Health issued a well-informed and ympathetic report (J. A. Glover) on the whole ubject in 1928. The National Health Insurance Acts appear at present to stand somewhat in the way f the adoption of their scheme (on which my own s based). To allow either to be adopted in its ntirety an amending Act would be desirable. although f all the approved societies concerned could show surplus on valuation they could, if they wished, ut the proposals into operation under Additional Benefit 16 of the 1928 Act.

2. *The social aspect.*—The State policy in this ountry is to assist voluntary effort. so that insurance nay be provided against both sickness and disable-nent—i.e., acute and chronic disease. The legislature s, therefore, presumably prepared *to meet* public vishes. but public opinion must be educated to expect nore in this matter. At present *the only "benefits"* applicable to rheumatism are: capitation fees for loctors for advice: chemists' bills paid *for insurance* practitioners' drug prescriptions; and cash allowances on doctors' certificates of incapacity or disablement. A few approved societies with surplus funds can pay *voluntarily* certain sums direct to medical institutions under the 1928 Act. This clause was added specifically to include physical treatment, and 79 approved societies have included this benefit during the past year and are believed to have found it satisfactory.

OBSERVATIONS.

1. The only methods of dealing with a disease which costs £17,000,000 per annum are, at present, analgesics and weekly "doles." Presumably because rheumatism does not kill its victims.

2. Preventive and other therapeutic measures are not provided, and therefore often believed not to exist.

3. In the case of tuberculosis (which costs the country less than rheumatism) the law provides for institutional treatment. Rheumatism needs this equally for its proper treatment.

4. The chief medical officer of the Ministry of Health recognised the preceding points in his report for 1925, and put forward suggestions then.

Arguments for Systematic National Control.

The reasons for dealing with chronic rheumatism systematically on a national scale include the following. The disease at present causes a large loss in money, and an immense amount of preventable suffering and crippledom. Nothing systematic is at present being done in England, whereas other countries—e.g., Germany and Sweden—find it worth their while to tackle the problem. Lay opinion is in favour of action, but lacks medical guidance, while research, which is very desirable in this group of diseases, could be stimulated and rendered possible on larger scale than at present. Attempts on a small scale in local areas (some of which are being planned) are likely to be less efficient than if they form part of large schemes, because they will probably have less money and possibly not use it to the best advantage; because they will have less medical and other encouragement and have less medical skill and experience at their disposal, and because they will probably overlap with other institutions. Any large movement should therefore be centralised, however loosely. Possibly there should be some central advisory body of medical and lay experts who can correlate the large amount of experience now available.

"Rheumatism is a burden to the country in two ways: (1) If patients have limited means they must be provided with medical aid. (2) If patients are unable to work, they must be supported financially. If a more far-seeing policy were adopted, *prevention* would also become a social responsibility" (R. F. Fox).

The basis of an active campaign (apart from the necessity for a definite scheme) would be early diagnosis. and the establishment of physical treatment clinics in towns. Provision should also be made for in-patient treatment, which is especially important in some of this group of diseases at certain stages. The London County Council has made a move in this direction by allocating ten municipal hospital beds for treatment and investigation at the British Red Cross Clinic for Rheumatism.

Arguments against the Establishment of Clinics.

The first argument against the clinic is "unnecessary expense." But in such a costly and painful disease group. if further efficient therapeutic help can be made available for the insured population, it would seem to be justified morally and also financially (by lessening subsequent invalidity pay). It may be said. again, that the value of clinics is not definitely known in this country. But a scheme such as that suggested below could be put into operation in London—as is partially already the case—and its value could be worked out by the approved societies. It might then be copied in other towns if, as appears almost certain, they approved the value of the methods.

---

* Abstract of a lecture delivered at the Royal Institute of Public Health on Feb. 24th.

Another argument against the scheme is that it would probably evoke opposition from insurance practitioners. The answers are :—

(1) "Clinics" are known to be suspect, but no practitioner need avail himself of the service suggested. It is designed, moreover, to increase their therapeutic resources in a disease in which they often find their ordinary resources are inadequate.

(2) Patients could only be referred for "courses" of treatment, and would therefore be automatically returned to their practitioners (as at Peto-place) after this had finished.

(3) Such treatment is not a substitute for ordinary methods of treatment but an additional method. Such institutions would therefore not "compete" with the insurance practitioner any more than do the voluntary hospitals. Ideally the clinics would actually be extra departments of voluntary hospitals; the practitioner would not, therefore, suffer financial loss by referring patients to them.

Lastly, it is suggested that possibly other diseases should also be singled out for special treatment. But such a scheme is necessary only in the case of a chronic disease which occurs on a scale large enough to merit the title of a social menace. These diseases are four in number :—

(1) Tuberculosis.—Efficient scheme already in force.
(2) Venereal diseases.—Efficient scheme already in force.
(3) Cancer.—Owing to dramatic appeal of this disease adequate voluntary effort is forthcoming.
(4) Chronic rheumatism.—The most costly of the three (to the country), but lacking in dramatic appeal because it is not fatal. Scheme suggested.

Outline of a Scheme.

The factors to be considered are *prevention* (predominantly a social question); *detection* (a mixed social and medical question); and *treatment* (predominantly a medical question).

PREVENTION.

Under this heading the following points may be briefly mentioned :—

1. *Exposure* to extremes of heat, cold, and moisture. Draughty offices, &c. Provide drying rooms, &c.
2. *Hygiene.*—Dietetic, e.g., "tea and bun habit"; beer; lead; general hygiene.
3. *Occupational fatigue.*—Mechanical trauma, such as trauma from undue or unilateral loads; for example, it is suggested that dock labourers should be limited by international agreement to loads of 150 lb., to save hips and backs. Undue or unilateral strains due to design or position of machinery, postural defects, provision of pit-head baths at mines, &c.
4. *Mental strain*, especially in women. Rest pauses where band conveyor is used. Variation of occupation. Recreation and sport.
5. *Housing.*—See Architects' B.M.A. report re juvenile rheumatism; damp-courses, situation of sites (M.O.H. has considerable power), sunlight, &c.
6. *Infection.*—Focal, and untreated traumatic sepsis. (Sunlight and breathing exercises for sedentary workers.)

Those responsible for prevention are primarily factory owners and managers, welfare workers and nurses, shop stewards and trades unions, factory inspectors, and the workers themselves; secondarily, medical men.

DETECTION.

The object is to get cases in an early and therefore curable stage. This can be done by coöperation between those responsible. Vocational guidance centres might aid by advising pre-rheumatics against unsuitable occupation. Points to be noted at this stage of disease are :—

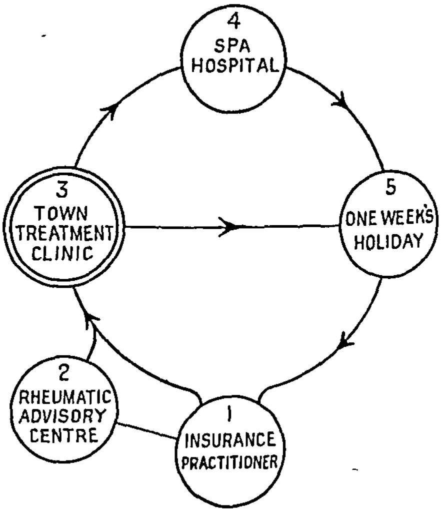
1. Women predominate over men sufferers.
2. Pains may at first be mild, transient, and variable. "Tingling" in limbs; "chilly subjects"; poor circulation.
3. General pallor and poor health common for considerable time previously (pre-rheumatic stage). Often rheumatic troubles at school.
4. "Fatigue factor" and "nerves" generally obvious.
5. Menstrual disturbances common. Dry skin.
6. Rheumatic family history common.
7. Bad teeth or frequent sore-throats, or "discharge" (in women). Climacteric.

(*a*) *In factories and the like* (supplementary to rest of scheme).—Where early detection on these lines is attempted, the effort should be specifically made by the works' doctor, who would deal at stated times with the diagnosis of doubtful cases; he would treat them or refer them for further investigation or specialist treatment at the clinic in the area. He should also from time to time meet the factory staff, and give a talk on the early signs and impress the need for early treatment or prevention. Such an organisation, which would be desirable in every community of workers numbering 2000 or more, might be termed a *prophylactic centre.*

(*b*) *In cities* (for general population outside factories).—The normal provision for diagnosis would be :—

1. The *insurance practitioner.*
2. The *Rheumatism Advisory Centre*, of which there would be two or more in every large town.
3. *Treatment clinic.* (One of the advisory centres should be in this building.)

Patients may thus, with the consent of their doctor, get advice in the area most convenient to them. If treatment proved necessary, they would be referred to the central treatment clinic with notes on their condition and requirements. Their cases would also, later, be "followed up" from the centre they first attended. Diagnosis would under this scheme be decentralised, and not treatment. This would be less expensive than the reverse.



1. *Insurance practitioner* who can refer his patient either to:
2. *Rheumatic advisory centre* in area, or direct to:
3. *Central treatment clinic*, where patient could receive (say) three courses of physical treatment, without stopping work. If further treatment appeared desirable, patient could go on to the
4. *Spa hospital*, where he could be treated up to two or three months.
5. *One week's holiday* at least is desirable, if possible, after treatment at either place.

Patient would then report back to the *practitioner.*

The insurance practitioner's rôle is chiefly early routine diagnosis, removal of obvious focal sepsis, general advice, and encouragement. The advisory centres would be established on the model of the various centres already available for juvenile rheumatics. and should be housed, if possible, in some building in medical use, where other clinics are held, and should be established if possible at the request and with the coöperation of the M.O.H. of the area (who might advertise it with his other clinics). It is essential that the insurance practitioners should be in sympathy and coöperation with the scheme, which is designed to increase their available therapeutic resources and to coöperate with them in preventing permanent invalidity. Cases should only be accepted on their recommendation. Each session at the centres should be held in weekly rotation, after normal working hours, by a member of the medical staff of the central treatment clinic, and cases referred by him for treatment to the clinic would be under his care during this period to ensure continuity. If the area served by these advisory centres extended beyond the towns, patients from outside could be supplied with a list of hostels or recommended addresses, where they could stay cheaply during the course of treatment and be near the clinic. In order that a complete diagnosis of all cases could be made at these centres, the clinic pathologist might attend for a short time at each session at the diagnostic centres to collect material for necessary tests.

TREATMENT.

Clinical material to be dealt with comprises early cases, non-curable cases which can be improved, and totally disabled cases.

Early cases would be dealt with by the town clinics where infective foci could be searched for and removed (if practitioner desires). There would be systematic physical treatment after working hours, so as to keep the patients at work during day. Two or three courses could be given with intervals between. They should then report back to their private doctor. If practicable, there should be an "after-cure" of one or two weeks at bracing health resort (not in "convalescent home"), if the patient is a "time-rate" worker, for such workers often cannot get a holiday otherwise. (Piece-workers can, by sacrificing pay for a period.) It may be advisable to change occupation, if this is obviously causative.

Cases no longer curable, but which can be much improved, can be dealt with by (*a*) town clinics, and (*b*) spa hospitals. The latter should give more freedom and provided occupation, and the stay could be prolonged up to two to three months in certain cases. In the provinces, where there is a spa hospital within easy reach of towns, this may take the place of a town clinic. Cases whose affection is chiefly in the legs and who find much difficulty, therefore, in attending as out-patients at a town clinic would be eligible even if not otherwise severe cases. After the patient leaves the spa hospital it might be desirable to arrange attendance at a re-education centre to train him for lighter employment. Machinery for provision of alternative employment might also be arranged. Compare the work of Jansen (Denmark) and Kahlmeter (Sweden) in getting borderline disabled cases back to work through in-patient sanatoriums outside towns in healthy places.

Totally disabled cases.—The possibilities would be: (*a*) palliative treatment at regular periods, and (*b*) accommodation in special institutions if the home conditions undesirable; possibly there might be special institutional piece-work, for which small sums might be paid. The cases in this category would not necessarily come into the present scheme.

The Three Therapeutic Agencies.

The three units chiefly concerned in this scheme are insurance practitioners, the town treatment clinics, and the spa hospitals. The function of these is: to diagnose cases early and carry out preliminaries; to cure or relieve; and (as concerns the clinics and hospitals) to teach and investigate. I have already spoken of the rôle of the insurance practitioner, but must deal in more detail with the others.

TOWN TREATMENT CLINICS.

(*a*) *Curative aspect*.—The clinics would be on hospital lines, and preferably not run by municipal or purely local bodies. They should provide all forms of treatment that are otherwise not available in area. These may include general bath treatments; general hot air and vapour rooms; general and local electrical treatments, including ultra-violet rays and massage; local mud and paraffin wax treatments; colonic lavage; vaccine and other injection therapy; and a dispensary.

If there is a general hospital in the area, overlapping should be avoided, and liaison made (usually most easily with the particular members of staff interested with whom cases may be exchanged). Methods which hospitals and practitioners are equipped to give—e.g., drugs and vaccines—should be subordinated, at the clinics, to methods less generally provided, such as baths and other physical methods. Public medical baths are available in a few industrial towns, and fuller use might be made of them. Specialists whose opinion will be often desirable at the clinics—such as orthopœdic and ear, nose, and throat surgeons, dentists, and gynæcologists—who are already on the staff of the area hospital, might consent to attend, say once weekly, to see patients referred to them. They would then refer the patients who needed treatment to their own hospital departments. This would also encourage liaison with the hospitals and outside practitioners.

The clinic should be staffed by two or more specialist physicians, since this leads to more progressive work than is done under a single medical director. Results can be watched and compared, and the clinic is of more value for post-graduate teaching purposes.

Pathological laboratory work may be provided for at the clinic, in which case a whole- or half-time pathologist and equipment will be needed, or may be undertaken by an outside laboratory at contract. The former plan is the better. The matron will control the treatment staff; male and female, who should all be chartered, and V.A.D.'s where available, should be used elsewhere and will save expense. There should be an almoner's department, from which patients can be followed up. This work inevitably becomes somewhat elaborate, owing to the time involved in following up such a chronic disease (often many years). It would be done best, probably, through the diagnostic centres which referred the patients originally.

By centralising these clinics into large towns, rather than by setting up large numbers of small clinics (as is at present the tendency), large numbers of patients would be seen, more experience gained, and in consequence better results achieved. More reliable statistics also become available. The value of such a centre is much enhanced if beds are available for treatment and investigation, and if easy reference of cases to the spa hospitals is possible.

The appointment system should be used both for consultations and treatments.

Most of the points referred to above are the outcome of experience at the B.R.C.S. Clinic for Rheumatism in Peto-place, and many of them are already embodied in the organisation of that clinic, which is only, it is to be hoped, the first of many other similar institutions, although strict standardisation is to be avoided.

Teaching and research.—Medical post-graduate teaching is very desirable, since no provision is made for teaching of physical medicine in medical curriculum, and physical methods need considerable skill and experience to get good results. They are, therefore, not so widely appreciated and used as they would otherwise be. If this were a success, universities might establish readerships or lectureships in the subject, possibly in connexion with the institution. Masseurs, masseuses, and nurses must be trained in order to provide a staff for the future use of the clinic and for other centres. (The C.S.S.M.G. run courses at Peto-place.)

Research is an urgent need in this branch of medicine. The subject of chronic rheumatism has never, until recently, inspired enthusiasm, except in few individuals, and is therefore most neglected. Besides medical research, lay research workers are needed to study such subjects as conditions of employment and environment. The Institute of Almoners have a whole-time research worker at Peto-place investigating the psychological and environmental antecedents of certain rheumatic patients.

SPA HOSPITALS.

These institutions, which are mostly foundations of considerable antiquity, were, until the nineteenth century, the only places where rheumatism was specifically dealt with. They treat some 3000 to

4000 patients a year, but for various reasons are not used at present to their full advantage (as pointed out by Sir George Newman in 1928). Their sphere of utility would be increased—

(a) If they could be brought into full coöperation with schemes for the preliminary town treatment of rheumatics, and spa treatment could, therefore, be included in the normal course of a majority of the cases which are no longer curable but which can be improved, and cases unable for any reason to attend town clinics as out-patients.

(b) If patients could be retained for longer periods.

(c) If, as previously mentioned, some scheme could be evolved whereby more freedom and definite occupation could be given to the patients.

The patients' energies are often normal, although hampered in expression by local limitation, and should be given an outlet, both physical and mental. Patients in these hospitals get the best treatment available, but are often bored; this is highly undesirable at the beginning of what is often a very chronic disease. This, if realised to be a real need, could fairly easily be remedied locally. Such bodies as the Workers' Educational Association and local dramatic societies could be called upon to play a part in instruction and entertainment.

Conclusion.

In conclusion, three paragraphs from the Ministry of Health report on "Chronic Arthritis" may be quoted in justification of some such scheme.

"Fundamental uncertainties can only be cleared up by a continuous and intensive study, from every point of view, of large numbers of patients in the early stages of the disease. To this end an organisation which includes full facilities for *assembling together sufficient patients, and for thorough* diagnosis, careful records, complete equipment for early and adequate treatment, and an effective system of following up seems essential. It would appear that to achieve such an organisation the provision of one or more special 'units' or institutions is necessary. (This paragraph was the stimulus which produced Peto-place.)

"A proportion of chronic arthritics (amounting to perhaps 10–15 per cent., and including many of those acute cases which occur in comparatively young female patients) are exceedingly intractable to treatment of any kind. These cases have produced an impression, which still survives in many quarters, both professional and lay, that chronic arthritis is an incurable disease.

"On the other hand, whilst no specific remedy is known, it would seem that a much larger proportion, perhaps one-third of all cases, can be cured, and more than another third *relieved to a greater or less extent by early appropriate* and skilful treatment. Far from chronic arthritis being incurable, there are few disease groups in which early and proper treatment is more necessary or more effective."

To summarise, for the efficient treatment of chronic arthritis in this country it is desirable:—

(1) That the subject be regarded as a proper field for specialised medical diagnosis and treatment, including the precise use of physical methods.

(2) That the coöperation of interested lay bodies be obtained (approved societies, &c.).

(3) That some definite scheme, incorporating both the medical and lay bodies concerned, be inaugurated. A skeleton scheme is suggested in some detail and deals separately with prevention, diagnosis, and *treatment centralised in towns. It could be put into* immediate partial operation without amendment of the National Health Insurance Acts.

(4) That re-education and amelioration for patients in the later stages of disease, and too advanced to return to work, but able to do light work, would be worth undertaking.

"Although many cases of arthritis cannot be cured, there are few indeed which cannot be relieved and the disease arrested with periodical courses of treatment" (Glover).

THE centenary dinner of Messrs. C. J. Hewlett and Son, Ltd., export druggists, was held on April 23rd, at the Abercorn Rooms, Bishopsgate, when about 140 guests were present under the chairmanship of Mr. Vivian C. Hewlett, F.C.S., grandson of the founder of the business. The toast of the firm was proposed by Dr. A. Cox, and supported by Mr. A. R. Melhuish, President of the Pharmaceutical Society. The chairman and Mr. E. J. Millard, managing director, replied. During the proceedings the staff presented the chairman with his portrait in oils.

NEW PREPARATIONS.

(1) RESYL (Clayton Aniline Co., Ltd., Southwark-street, London, S.E.).—Resyl "Ciba" is a syrup prepared by the Society of Chemical Industry, Basle, containing glycero-guaiacol ether for use as a guaiacol substitute in the treatment of inflammatory conditions of the respiratory tract, the claims made for it being that it is readily absorbed, antiseptic, facilitates expectoration, and lessens irritation. The syrup is put up in bottles of 200 g. It may be taken undiluted or mixed with water, milk, tea, or other fluids, and the dose for adults is 3–5 teaspoonfuls daily, while children may take from 1–3 teaspoonfuls. The carton contains the warning that the content is to be used only in accordance with the directions of the doctor.—(2) PERCAINAL CIBA, also *prepared by the Society of Chemical Industry,* contains percaine incorporated with a bland base which is readily absorbed, distilled extract of witch-hazel (6 per cent.), and a solution of aluminium formate (10 per cent.), the ingredients thus justifying the claims for antiphlogistic and astringent properties. It has been designed, accordingly, for application to the skin and mucous surfaces in eczema, herpes, pruritus, hæmorrhoids, and cracked nipples. It is put up conveniently in collapsible tubes containing 40 g.

ALPHIDINE (Oppenheimer, Son and Co., Ltd., Handforth Laboratories, Clapham-road, London, S.W.).—This preparation is described as a non-toxic, non-irritant, assimilable allotropic form of iodine which produces a colloidal solution in water, and clinical reports, from England and America, would suggets therapeutic activity and absence of manifestations of depression. It has been tested on arthritic patients with promising results, and improvement has been noted in pulmonary tuberculosis, and in obesity weight has been reduced by loss of abdominal fat. Its employment is indicated in all cases where iodine or the iodides are called for. The dose is from one to four pulverettes three times daily, and they can be obtained in bottles of 50, 100, 500, and 1000.

KARO (Corn Products Co., Ltd., Bush House, Aldwych, London, W.C.) has the following percentage composition, according to the manufacturers' statement: dextrine and malto-dextrine, 35·41 (46·08); *maltose, 10·10 (13·17); dextrose, 23·31 (30·34);* other carbohydrates, 0·50 (0·65); sucrose, 2·50 (3·25); invert, 3·50 (4·55); ash, 1·51 (1·96); water, 23·17. (The figures in parentheses show dry basis.) One fluid ounce (or two tablespoonfuls) of Karo is equal to one avoirdupois ounce of sugar and provides 120 calories. The substance, which is in the form of a syrup, has for its chief carbohydrate dextrin, which is non-irritating and fermentable with difficulty. Clinical reports would indicate its value in the feeding of undernourished and sick infants. It is manufactured at Trafford Park, Manchester, and is put up in 2 lb. tins, upon which are printed instructions for its use in the case of infants, children, and adults, together with a feeding table for average *babies.*

IN connexion with a scheme for providing free classes for unemployed men and women, the name of a doctor able and willing to spare an hour or two on Friday afternoons to take a first-aid class is wanted. Any medical man or woman who could help is asked to communicate with the Principal, Morley College for Working Men and Women, 61, Westminster Bridge-road, London, S.E. 1.

Mr. Watson Turnbull (21, Sheen-road, Richmond, Surrey) writes: I have produced a series of dry-point portraits of a number of prominent personages in British medical science, among them being Lord Lister, Sir J. Y. Simpson, Sir Jas. Paget, *Sir Patrick* Manson, Sir Arthur Keith, and Sir Ronald Ross. The impressions are strictly limited to 25 from each plate. An impression from the Sir A. Keith plate is exhibited in the 1932 Salon, Paris.

ADDRESSES AND ORIGINAL ARTICLES

ON STERILITY.*

y Victor Bonney, M.S. Lond., F.R.C.S. Eng.,
F.R.A.C.S.,

ETRIC AND GYNÆCOLOGICAL SURGEON TO THE MIDDLESEX
SPITAL; SURGEON TO THE CHELSEA HOSPITAL FOR WOMEN.

HE requisites for conception are a fertilisable egg- , a potent sperm, an uninterrupted trackway ng which they may meet, and a surface suitable the implantation of the oösperm.

The Egg-Cell.

Modern research is agreed that the human egg- l escapes from the follicle about midway between o menstrual periods, but how long it takes descend into the uterus is not known with rtainty. Under normal circumstances only one hiscence occurs a month. In certain individuals hiscence either does not occur at all or only very dom, either because the ovaries are naturally fective or have been damaged by inflammation new growth, or because, though healthy, their ulating function is in abeyance owing to hormonal ficiency. The sterility produced by any of these uses is absolute so long as the cause persists.

Sterility may also be relative, for the results of ock-breeding show that amongst a species some males are infertile to certain of the males, though ey are fertile to the rest, and this almost certainly olds good for human beings, though it is difficult to rove in individual cases. Arthur Robinson in a lassical paper showed that in animals the fertilised vum may for no known cause perish at a very arly period after fertilisation before any signs of regnancy have had time to declare themselves. This probably happens with more or less frequency n most married women, and constantly in some, who re then labelled as sterile, though in fact they are not really so.

The Sperm.

It is generally agreed that fusion between the egg-cell and sperm takes place in the tube, but how long it takes the human sperm to ascend thus far is not accurately known, and still less the period of time over which, having gained the tube, it can maintain itself there.

Sperm-impotence may be absolute owing to deficient vitality of the male element, or it may be relative just as egg-cell infertility may be. Further, the sperm though healthy at the start of its journey may have its potency destroyed or weakened by the toxic effect of abnormal discharge from the female passages. We know very little about this, for the task of mixing together vaginal secretion and semen and watching what happens under the microscope is distasteful, but such researches carried out on the Continent indicate that the toxic effect of vaginal discharge can be an important factor in sterility. I have always thought that the phenomenon of profluvium seminis must be due to the sperms retreating en masse from an environment hostile to them.

Though the sperm be potent its deposition may be defective, either on account of weakness of the male organ or deformity such as hypospadias. That its powers of ascent are at times remarkable is shown by the fact that deposition on the vulva may be followed by pregnancy, and I have seen two cases in which conception occurred though the woman's clothes barred direct contact.

The Trackway.

The female genital canal is divisible into (1) the ovarian segment; (2) the peritoneal segment; (3) the uterine segment; (4) the cervical segment; and (5) the vaginal segment, and if any one of them be occluded pregnancy cannot occur.

Ovarian segment.—That the follicle after dehiscence forms the upper end of the female genital canal is proved by the occurrence of ovarian pregnancy. Failure of dehiscence may be due to some primary defect in the ovarian structure, but more commonly it is the result of peripheral sclerosis or adhesions of inflammatory origin.

Peritoneal segment.—The fact that the peritoneal cavity itself forms part of the genital trackway, is not, I think, sufficiently appreciated, and yet the distance the ovum has to travel from the follicle to reach the fimbriated extremity of the tube is in most cases the best part of an inch, whilst in those instances where pregnancy occurs in a woman possessing only one ovary and one tube and those on opposite sides, the distance travelled must be two inches or more. The idea that the fimbriated extremity clasps the ovary is no longer entertained, as far as regards human beings at all events, nor does there obtain in our species an obvious mechanism for practically compelling the ovum along the right path such as exists in certain of the lower animals. The relation borne by the fimbriated extremity to the ovary varies immensely in different women. In some it is closely applied to it, but in others it hangs pendant below and widely removed from it. Moreover, the point at which dehiscence occurs on the surface of the ovaries varies. One might have opined that Nature would arrange that it invariably took place on that part of the surface closest to the abdominal ostium, but such is not the case. I have often seen a recently dehisced follicle situated at the inner pole just outside the ovario-uterine ligament and as far away from the abdominal ostium as possible. In short, considering the purpose for which the structures concerned exist I cannot conceive of a more imperfect mechanism, and never cease to marvel at the wonder of conception achieved in spite of such discouragements. It would appear certain therefore that the ovular wastage along the peritoneal segment of the trackway must normally be large, whilst under abnormal conditions, such as adhesions of omentum, appendices epiploicæ or intestine, every egg-cell escaped from the ovary must perish in the abdominal cavity.

Tubal segment.—Our knowledge of tubal occlusion as a cause of sterility has made enormous strides since the invention by Rubin of the tubal insufflation test. The apparatus I use is simpler than Rubin's and has, I think, certain advantages over it. It consists of a hollow uterine dilator to which a rubber bulb and sphygmomanometer is attached by means of lengths of pressure tubing. The cervix is dilated by ordinary uterine dilators to a size just less than the size of the hollow dilator, so that when this is introduced it fits the cervix too tightly for air leakage to occur. The bulb is then compressed with the hand and the pressure applied noted by observing the manometer. With normally patent tubes air passes through at a pressure of 50 mm. or less. Where the pressure has to be raised to 100 mm. or over there is a degree of obstruction. This may be due to abnormal smallness of the tubes or to occlusion of one tube only or to kinks or strictures or partial closure of the abdominal ostia. If in spite of the pressure being raised to 200 mm. no air passes, bilateral tubal occlusion in all probability is present. The patient, having been anæsthetised, should be in the lithotomy position and slightly tilted head downwards so that the vagina can be filled with weak mercurial solution which by bubbling will disclose any leakage of air backwards through the cervix. Tubal insufflation is performed by some in the consulting room without an anæsthetic, but I personally disapprove of it, for apart from the fact that sooner or later this practice will result in the hurried carrying up to a bedroom of a fainting or even a dead woman, it is in my opinion impossible under such conditions to be sure of preventing leakage backwards from the cervix, and unless this can be achieved with certainty, the whole proceeding is useless. It goes without saying that the test should never be carried out on a patient whose vagina or cervix presents any suspicion of infection, and it is a wise precaution to prohibit marital relations for some time beforehand.

---

* Read before the Windsor Medical Society.

Lipiodol.—Of recent years another method of ascertaining the state of the tubes has been invented, which consists in injecting lipiodol into the uterine cavity from whence, if the uterine ostia are patent, it passes into the tubes and, if the abdominal ostia also are patent, into the abdominal cavity. The patient is then radiographed and the position and shape of the shadows shows whether the tubes are occluded or not. The method has the advantage over the more simple insufflation that it can show what insufflation cannot show—namely, whether one or both tubes are patent, and also in the event of occlusion, whether the block is at the inner or outer ostium. Such knowledge is, however, of little practical use because in a case of sterility in which investigation either by insufflation or lipiodol shows that though not normally patent a partial degree of patency exists, no operation is indicated, whereas if total occlusion is revealed either by one method or the other nothing less than an endeavour to open up the closed tubes is of any use.

The causes of tubal occlusion are various, first amongst them being salpingitis which may block the lumen at various points, the two most common sites being the inner and outer ostia. In some cases long lengths or even the whole length of the lumen may be obliterated. Next in importance is kinkage, the kinks most often affecting the narrow isthmic portion. They are easily overlooked if one relies merely on sight, but they show up immediately air is blown down the tube from the abdominal ostia. For this purpose I employ a special insufflator, consisting of a bulb to which is attached a nozzle that just passes through the outer ostium. An ophthalmic canaliculus-catheter can be screwed on to the nozzle if the operator wishes to pass the instrument into the narrow isthmic portion of the tube. If a tube is freely patent air can easily be squeezed down it into the uterus with a characteristic gurgle.

The commonest cause of tubal kinkage is retroversion, and this fact largely explains the frequency with which sterility is associated with it.

Finally, the tubes may be congenitally small and narrow so that air scarcely passes through them, or not at all.

Uterine segment.—The uterine cavity is so large that nothing short of a tumour of considerable size in its interior will suffice to block it. Of such tumours fibroids form the vast proportion. Besides occlusion of the uterine cavity by a fibroid these tumours may by the deformity they cause obstruct the tubo-uterine junction, and beyond this they are deterrent to conception for reasons at present unknown to us.

Sterility is often ascribed to the uterus being "infantile," but a moment's thought will show this to be an error, for the oösperm can graft in the isthmus of the tube which is far smaller than the smallest "infantile" uterus. That sterility often accompanies a small uterus is due to the fact that the tubes in such patients are often congenitally impervious, or only poorly pervious as I have proved by abdominal exploration on a number of occasions. Moreover, deficient development of the uterus is often accompanied by deficient development of the ovaries, though not by any means always so, for I have five times performed Baldwin's operation for congenital absence of the uterus and vagina, and in each of the patients the ovaries were conspicuously normal.

Cervical segment.—Absolute obstruction of the cervical canal is very rare, but undue narrowness is common. Dilatation of the cervix for the cure of sterility has been a standard operation for a great many years, though having regard to the small size of the sperm in relation even to the narrowest cervical canal it is difficult to see how it acts. That patients often become pregnant after it is not in itself proof of the efficacy of the procedure. Consider, for instance, the case of a healthy young woman of 26 married four years to a healthy young man and no baby yet. It is most unlikely that this girl will not sooner or later conceive without any interference. If it came to betting, none of us would like to wager against that event unless we could get exceptional odds. Nevertheless, the cervix is dilated and six months afterwards the patient conceives. She and her husband will be positive that it was the result of the operation. But are we to record a success?

Great elongation of the cervix may prevent pregnancy because the semen is deposited above it, but I am doubtful whether the tilting of the cervix that occurs in retroversion can have any material effect. Tumours of the cervix such as polyps or small fibroids must obviously act as obturators.

Vaginal segment.—The cavity of the vagina is so large that its total occlusion except by congenital defect is rare. The so-called "imperforate hymen" is the best known example of this. Narrowness of the vaginal entrance sufficient to prevent coitus is, on the other hand, extremely common. In a few cases this narrowness is entirely due to muscular spasm, but as a rule a real narrowness is the basis of the dyspareunia, the muscular spasm being secondary to the pain evoked by the attempted act.

The Site for Implantation.

It is generally considered that certain cases of sterility are due to the endometrium being structurally unsuitable for the oösperm to graft upon. When, however, we consider that grafting may occur into the substance of the ovary, the wall of the tube, and even the peritoneum itself, tissues differing profoundly not only from the endometrium but from one another, it seems difficult to believe that comparatively slight histological changes in the lining of the uterus could completely check the activities of the trophoblast. It seems to me more probable that the fault in these cases lies not with the structure of the endometria ie, but with a change in its secretion whereby it omes toxic to the oösperm.. Fertilisation of the cell normally takes place in the tube and the perm has already begun to grow and divide by the e it enters the uterus. Until it has grafted into endometrium its nutriment would appear to be ained from the tubal and uterine secretions, and can well imagine that these, if abnormal, might son instead of nourishing it. The matter is of ctical importance in regard to the question of the ity of curetting in cases of sterility.

Investigation.

n all cases of sterility with no obvious cause arent the husband should be examined both regards his physical condition and the state of semen. As regards this last, I feel sure that only reliable way is to do it microscopically his own house almost immediately after it been passed. A strictly scientific investi- or would then proceed to mix the semen with some the upper vaginal discharge collected in a pipette l watch the behaviour of the sperm under these ditions. This, however, is not usually done.

he woman must be investigated like any other æcological case by questioning and physical mination and, this completed, the tubal insuffla- n test should be carried out. I have already stated t in my opinion this should always be performed ler an anæsthetic, and the question therefore arises ether or not the surgeon should advise his patient let him proceed at once to abdominal section in event of the test indicating that both tubes are sed. It is important in this connexion to bear in d that failure to get air to pass along the tubes, ugh usually due to fixed conditions, may be endent on temporary causes, such as thickening the cornual endometrium, or even, it is said, scular spasm at the tubo-uterine junction. If her of these two latter conditions obtains it will found on opening the abdomen that air can be ced down the tube though it cannot be forced wards.

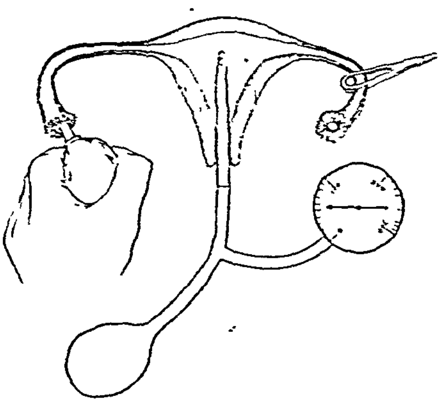
My experience of abdominal operations for sterility s taught me that blockage of this character is not mmon. but nevertheless in a case in which tubal nfflation indicates that both tubes are blocked, it is en advisable to repeat the test in a month and only oceed to open the abdomen if at this second time trying air still will not pass. Many women, though ey are anxious to have a child, do not desire it fficiently to make them willing to undergo an dominal operation for the sake of the possibility having one.

On the other hand, there are cases in which the esence of marked retroflexion, or uterine fibroids, a thickening in the region of the tubes, or a past story strongly pointing to salpingitis makes it practi- lly certain that the failure of air to pass is due to a ed condition, and in such repetition of the test is necessary before opening the abdomen.

Remedial Measures.

Reopening the tubes.—Surgical operations for the rpose of reopening closed tubes have only been actised of recent years, but they have already vealed a number of interesting facts with which næcology was previously unacquainted. The neral procedure is as follows: The patient first placed in the lithotomy position. the bal inflation apparatus is inserted, and the tency of the tubes tested. If air will not pass, the vagina is packed with sterile gauze so as to keep the hollow dilator in the uterus in position, and the patient being moved into the Trendelenburg posture, the abdomen is opened. The intestines having been packed off from the pelvis a self-retaining retractor is inserted and the tubes and ovaries, after being inspected and felt, are brought up into positions in which their whole length is plainly seen, adhesions being separated if necessary. A light forceps is now placed on one tube so as to occlude it. An assistant now squeezes the bulb of the insufflator in the uterus whilst the surgeon watches the effect on the unclamped tube. If it is patent the air is seen and heard to pass out of the abdominal ostia. If the abdominal ostium alone is closed the tubes swell up by the pressure of the imprisoned air. If the point of obstruction is further along the tube only that part on the uterine side of the obstruction swells. If the block is at the uterine ostium no change at all occurs in the tube. If the abdominal ostium is open the small bulb insufflator already described should now be inserted and air squeezed into the tube from above. If any air at all passes into the uterus the needle of the manometer attached to the insufflator in the uterus will be seen to rise, because the air forced into the uterine cavity can neither escape through the cervix blocked by the hollow dilator nor through the opposite tube blocked by the forceps. (Fig. 1.) I have already stated that if a tube is freely patent air forced down it can be heard and felt to pass into the uterus, but this is not the case in low degrees of patency which will be missed if insufflation from above is carried out without the insufflator in the uterus. The forceps compressing the opposite tube is then taken off and applied to the tube already tested and the proceedings described are then repeated on the untested side.

FIG. 1.

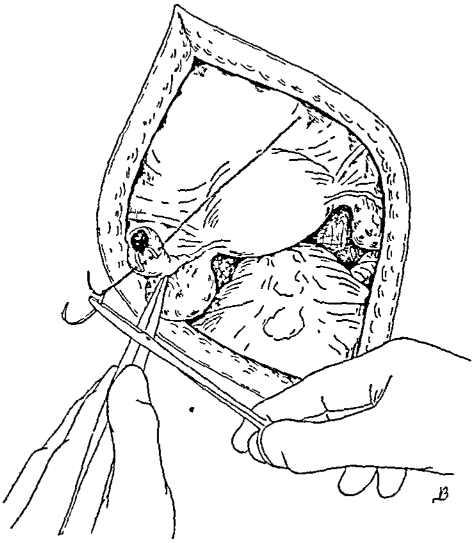


Showing how air blown into the tube from above registers on the manometer below.

Blockage at the abdominal ostium only is the easiest variety of obstruction to treat, requiring simple salpingostomy. The extremity of the tube should be separated from its attachment to the ovary by dividing the ovarian fimbria and the bulbous end slit sufficiently to allow of a cuff being turned back (like the cuff of a dressing-gown sleeve) and fastened so with a few fine catgut sutures. (Fig. 2.) Kinks are a more difficult problem, but usually by pulling them, aided by minute incisions through the peritoneal bands holding them, the tube can be straightened out and air got to pass.

Blockage at the uterine ostium requires for its satisfactory correction reimplantation of the tubes into the uterus. I have long given up trying to pass threads of catgut down the tube into the uterus, being certain that nine times out of ten a false passage is made. The technique of the operation, which I first performed in 1921, is as follows: I begin by arresting the blood flow through the uterus by placing my myomectomy clamp on its lower segment and ring forceps on each ovariopelvic ligament, the insufflator in the uterus having been first removed. One tube is now dissected out of its corresponding cornu and its patency tested by the small bulb insufflator. (Fig. 3.) If no air passes, a small piece of its inner end is cut off with scissors and the tube tested again. If still no air passes, another small piece is cut off and so on until air does pass. You then have a length of tube freely patent, and it is this that you are going to implant. The same proceedings are then carried out on the opposite side. The fundus of the uterus is now incised transversely from cornu to cornu until the cavity is opened. The inner end of each tube is now laid into its corresponding cornu and fastened there by fine catgut sutures (Fig. 4), after which the incision in the uterus is closed by interrupted catgut sutures. Finally, each tube is sutured to the outer surface of the uterus at the point where it passes into its substance.

FIG. 2.



Fixing the cuff in salpingostomy.

Whichever method be employed to open up the tubes, all adhesions round the ovaries should be cleared away, and in most cases it is advisable to raise the uterus and appendages out of the pelvis by shortening the round ligaments or ventrofixing the uterus. If the uterus is retroverted this should of course be done.

Removal of fibroids.—Fibroids causing sterility should be treated by myomectomy—an operation which occupies a very different position from what it did 20 years ago. It is now possible to conserve the uterus in almost every case, leaving an organ capable of child-bearing. The largest number of fibroids that I have removed from a uterus which subsequent to the operation bore a child is 32. I would refer those interested in the technique of this operation and its results as regards pregnancy to my Hunterian Lecture (THE LANCET, 1931, i., 171).

Dilatation of the cervix.—I am chary of ascribing results to an operation merely because they follow it; nevertheless, I am of opinion that dilatation of the cervix does favour conception though not with anything like the frequency commonly claimed. As quite a number of the young married women wanting children also suffer from "first day" dysmenorrhœa, dilatation often has a double advantage. Moreover, dilatation forms an essential part of tube insufflation which nowadays should always be performed in a case of sterility. To merely dilate the cervix and leave the tubes untested is inadequate practice.

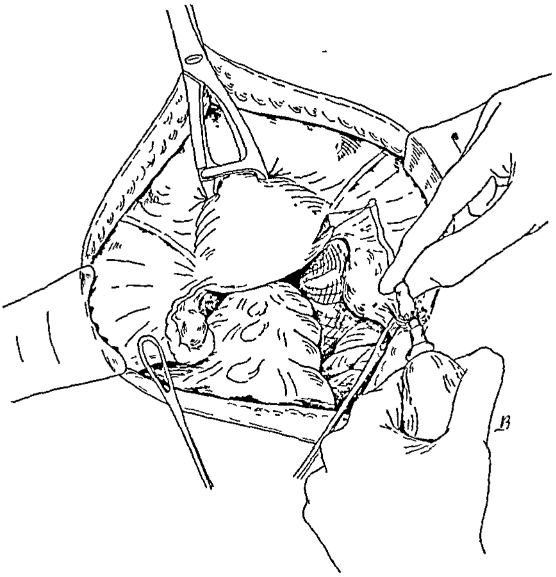
Curettage.—Unless there are symptoms such as menorrhagia indicative of endometrial abnormality, I see no object in curetting the uterus.

Tubal insufflation as a cure.—It is believed by some that insufflating the tubes increases the likelihood of a woman becoming pregnant. The only apparent ground for this belief is the fact that women sometimes conceive shortly after insufflation. From a now-extensive experience in viewing the actual condition of the tubes in cases of sterility I am of opinion that it is impossible except perhaps in very rare instances. Patients, of course, accept the association.

Enlargement of the vaginal orifice.—In some cases the failure to conceive is due to imperfect penetration during intercourse. In nearly all of them the vaginal orifice is unduly narrow and rigid and the pain evoked produces a quite natural resistive spasm which increases the difficulty. Women of this type are frequently hypersensitive and overstrung, but it is a mistake to regard the dyspareunia as of purely nervous origin. I have long given up merely stretching the parts under an anæsthetic. It does little or no good as a rule and the failure only increases the patient's concern. The orifice should be deliberately enlarged by a plastic operation. I know few operations that more uniformly yield a happy result.

Stimulating the ovaries.—The fact that the ovaries are not producing egg-cells can only be proved by inspection through an abdominal incision. It may be surmised, however, when a woman normal on physical examination and whose tubes have been proved to be patent fails to conceive though her partner is a perfectly normal man. Even in such, however, relative infertility, loss of the egg-cell during its transperitoneal passage, or very early death of the oösperum, are equal possibilities. Modern research teaches that the ovaries in certain animals are under the influence of two hormones secreted by the anterior lobe of the pituitary gland, and that

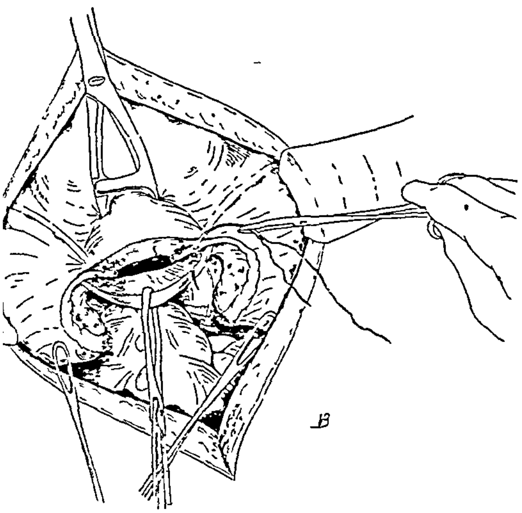
FIG. 3.



Implanting the tubes. Testing the separated tube.

of these administered experimentally greatly 'eases the ovulating function of the ovary. Of ınt years it has become common practice to treat :ile women by various endocrine extracts in the ›e that they will stimulate the ovaries to produce

FIG. 4.



mplanting the tubes. Fixing the tubes into the uterus.

›t only "bigger and better" egg-cells, but more of ıem. Biochemists have succeeded in obtaining ıese hormones in purity sufficient to give definite sults when administered to certain animals, but it is a ng cry from rats and mice to human beings, and there no evidence at all that these extracts produce any fects on women. One reason perhaps is the fact :cently stated by an expert worker in this field that dequate dosage of a woman with hormones of proved ctivity would cost several thousand pounds! 'regnancy sometimes follows the administration of ndocrine extracts just as it does after mud-baths, pa treatment, or suggestion, but let us be on our uard against that credulity which we so readily ecognise when it is lay but only perceive with effort vhen it is professional.

Altering the vaginal discharge.—Our knowledge oncerning the effect of abnormal uterine or vaginal lischarge on the sperm is very imperfect. It is said hat a highly acid state of these discharges is inimical, ınd on that ground frequent. and large alkaline rrigations of the vagina are advised. Until some 'eliable scientific work on this subject is carried ›ut measures of this sort are more or less empirical. They do not, however, do any harm.

Artificial insemination.—The sperms are not naturally injected into the uterus; they find their way of their own accord. The only condition I can imagine in which direct deposition into the uterus would be helpful is when the vaginal discharge ıs toxic to the sperm but the uterine discharge is not. The great drawback to artificial insemination of the uterus is the infrequency with which it can be carried out. A married couple who only had relations once every six months would probably have to wait a long time before having a child. To my mind a far better procedure is injection of the semen into the upper vagina by means of a syringe. The husband and wife should be instructed how to do this by themselves, so that it can be carried out frequently.

STONES IN THE COMMON BILE-DUCT.*

BY R. P. ROWLANDS, O.B.E., M.S. LOND.,
SURGEON TO GUY'S HOSPITAL; VICE-PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

THIS lecture is based upon 116 operations (choledochotomies) for stones in the common bile-duct performed by myself during the last 20 years; 61 of these were at Guy's Hospital and 55 in my private practice.

With rare exceptions gall-stones form only in the gall-bladder where the bile becomes very greatly concentrated by absorption. In the course of time they may migrate to other parts, especially into the common bile-duct. But only the smallest stones can pass through the normal cystic duct, whose channel is very narrow—only one-tenth of an inch in diameter—and tortuous from valvulation of its mucosa. For larger stones to pass, the cystic duct has to dilate as a result of chronic inflammatory softening and repeated attacks of colic. Therefore, in the large majority of cases cholelithiasis can be cured by cholecystectomy long before the common bile-duct becomes affected. Jaundice and cholangitis due to gall-stones can be thus prevented, and this is very desirable because operations upon the common duct, especially in the presence of jaundice and infection, are very far more dangerous than removal of the gall-bladder in early cases.

It is curious that many medical men still believe that jaundice is almost a necessary sign of gall-stones, whereas in reality it is a rare and late sign. Only one-fifth of my 666 cases of gall-stones had calculi in the common bile-duct, and by no means all of these had jaundice. Stones may lie in the common bile-duct for years without obstructing enough to cause jaundice—attacks of complete obstruction and colic, if any, being often of short duration. This fallacy too frequently leads to deplorable delay in the diagnosis of gall-stones, and condemns some patients to many years of unnecessary suffering, and allows dangerous complications, especially infection and jaundice, to develop.

Some of these avoidable complications may be mentioned in more detail: (1) Chronic, acute, suppurative, and gangrenous cholecystitis, with perforation causing local or diffuse peritonitis. (2) Chronic septicæmia; portal pyæmia. (3) Jaundice with infective or suppurative cholangitis. (4) Pancreatitis, acute, subacute or chronic. (5) Cancer[1] of the gall-bladder or bile-ducts, which develops in at least 5 per cent. of all cases of gall-stones. (6) Osteo-arthritis. (7) Cardiac degeneration. (8) Cerebral toxæmia, occasionally causing insanity.

Diagnosis.

The diagnosis of stones in the common bile-duct depends chiefly upon the association of repeated attacks of typical biliary colic, with jaundice of an intermittent or remittent type. Rarely is there any enlargement of the gall-bladder, as Courvoisier pointed out many years ago. Occasionally there may be no colic, this being replaced by intolerable nausea, with faintness and perhaps shivering. Sometimes jaundice is absent because the attacks of obstruction are not long enough to cause it. Here van den Bergh's test for bile-pigment in the blood is of great value. Naunyn pointed out that the duration of jaundice

only "bigger and better" egg-cells, but more of m. Biochemists have succeeded in obtaining e hormones in purity sufficient to give definite ults when administered to certain animals, but it is a g cry from rats and mice to human beings, and there no evidence at all that these extracts produce any ects on women. One reason perhaps is the fact ently stated by an expert worker in this field that equate dosage of a woman with hormones of proved tivity would cost several thousand pounds! egnancy sometimes follows the administration of docrine extracts just as it does after mud-baths. a treatment, or suggestion, but let us be on our ard against that credulity which we so readily cognise when it is lay but only perceive with effort hen it is professional.

Altering the vaginal discharge.—Our knowledge ncerning the effect of abnormal uterine or vaginal scharge on the sperm is very imperfect. It is said at a highly acid state of these discharges is inimical, d on that ground frequent, and large alkaline rigations of the vagina are advised. Until some liable scientific work on this subject is carried ut measures of this sort are more or less empirical. hey do not, however, do any harm.

Artificial insemination.—The sperms are not aturally injected into the uterus; they find their ay of their own accord. The only condition I an imagine in which direct deposition into the terus would be helpful is when the vaginal discharge toxic to the sperm but the uterine discharge is not. he great drawback to artificial insemination of the terus is the infrequency with which it can be carried ut. A married couple who only had relations once very six months would probably have to wait a ong time before having a child. To my mind a ar better procedure is injection of the semen into he upper vagina by means of a syringe. The usband and wife should be instructed how to do this by themselves, so that it can be carried out requently.

STONES IN THE COMMON BILE-DUCT.[*]

By R. P. ROWLANDS, O.B.E., M.S. LOND.,
SURGEON TO GUY'S HOSPITAL; VICE-PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

THIS lecture is based upon 116 operations (choledochotomies) for stones in the common bile-duct performed by myself during the last 20 years; 61 of these were at Guy's Hospital and 55 in my private practice.

With rare exceptions gall-stones form only in the gall-bladder where the bile becomes very greatly concentrated by absorption. In the course of time they may migrate to other parts, especially into the common bile-duct. But only the smallest stones can pass through the normal cystic duct, whose channel is very narrow—only one-tenth of an inch in diameter—and tortuous from valvulation of its mucosa. For larger stones to pass, the cystic duct has to dilate as a result of chronic inflammatory softening and repeated attacks of colic. Therefore, in the large majority of cases cholelithiasis can be cured by cholecystectomy long before the common bile-duct becomes affected. Jaundice and cholangitis due to gall-stones can be thus prevented, and this is very desirable because operations upon the common duct, especially in the presence of jaundice and infection, are very far more dangerous than removal of the gall-bladder in early cases.

It is curious that many medical men still believe that jaundice is almost a necessary sign of gall-stones, whereas in reality it is a rare and late sign. Only one-fifth of my 666 cases of gall-stones had calculi in the common bile-duct, and by no means all of these had jaundice. Stones may lie in the common bile-duct for years without obstructing enough to cause jaundice—attacks of complete obstruction and colic, if any, being often of short duration. This fallacy too frequently leads to deplorable delay in the diagnosis of gall-stones, and condemns some patients to many years of unnecessary suffering, and allows dangerous complications, especially infection and jaundice, to develop.

Some of these avoidable complications may be mentioned in more detail: (1) Chronic, acute, suppurative, and gangrenous cholecystitis, with perforation causing local or diffuse peritonitis. (2) Chronic septicæmia; portal pyæmia. (3) Jaundice with infective or suppurative cholangitis. (4) Pancreatitis, acute, subacute or chronic. (5) Cancer[1] of the gall-bladder or bile-ducts, which develops in at least 5 per cent. of all cases of gall-stones. (6) Osteo-arthritis. (7) Cardiac degeneration. (8) Cerebral toxæmia, occasionally causing insanity.

Diagnosis.

The diagnosis of stones in the common bile-duct depends chiefly upon the association of repeated attacks of typical biliary colic, with jaundice of an intermittent or remittent type. Rarely is there any enlargement of the gall-bladder, as Courvoisier pointed out many years ago. Occasionally there may be no colic, this being replaced by intolerable nausea, with faintness and perhaps shivering. Sometimes jaundice is absent because the attacks of obstruction are not long enough to cause it. Here van den Bergh's test for bile-pigment in the blood is of great value. Naunyn pointed out that the duration of jaundice for more than a year is in favour of stone, but I have seen jaundice due to carcinoma at the duodenal papilla last nearly two years. Shivering, with fever and rigors, complicating jaundice and colic, indicates infective or suppurative cholangitis. These attacks often recur and are very suggestive of stones in the common bile-duct, but they have too often been attributed to malaria.

---

[*] A Clinical Lecture delivered at Guy's Hospital.

I have known other obstructions of the bile-ducts mistaken for gall-stones, such as :—

(1) Organising blood clot[2]
(2) Small hydatid daughter cyst
(3) Round-worm
(4) Papilloma
(5) Papillary carcinoma
} in the common bile or common hepatic duct.

(6) Carcinoma of the common hepatic duct. Here there is no enlargement of the gall-bladder, which makes it resemble stone in the common bile-duct, especially as it often causes severe pain.

(7) Carcinoma of the head of the pancreas. Chronic pancreatitis. Hydatid cysts, aneurysm, tumours or other things pressing on the common bile-duct. These cause enlargement of the gall-bladder and of the liver.

(8) Carcinomata at or near the duodenal papilla or of the ampulla of Vater have all given trouble in diagnosis ; but with all of these the jaundice is chronic and rarely remittent. With cirrhosis of the liver the jaundice is continuous, although not severe, and the pain is that of peri-hepatitis and not typical biliary colic. The history, when not concealed, and the facial appearance, may be characteristic of cirrhosis of the liver. The jaundice of carcinoma of the liver, acute yellow atrophy, and other forms of toxic jaundice, have been mistaken for that due to stones in the common bile-duct.

Indication for Operation.

When the symptoms and signs point strongly to the presence of calculous obstruction of the common bile-duct, an operation is indicated whenever the condition of the patient allows it, for there is very little hope of cure by medical treatment or by waiting, although the stone sometimes at long last ulcerates through and is discharged into the duodenum.

But it is usually wise to defer operation until the quiet period—i.e., until jaundice and especially fever have abated. Operations upon the common duct are much safer when undertaken in the quiet period, but when colic and jaundice continue indefinitely without remission it is necessary to operate without waiting too long for a quiet period, before the patient has wasted unduly and has become unusually liable to bleed or to become comatose after operation.

Occasionally a stone firmly impacted in the common bile-duct causes sloughing and perforation of the duct with local or even diffuse peritonitis. When the cause of chronic jaundice is uncertain it is generally wise to explore, and I have often been rewarded in such cases by finding one or more stones in the common bile-duct. Moreover, if no stone, but some irremovable cause of obstruction is found, a cholecyst-gastrostomy can be made to overcome the jaundice and the intolerable itching and anorexia which make the patient so unhappy and always shorten his life.

It is very rarely wise to allow many repetitions of biliary colic with jaundice, although it may be reasonable to hold the hand after the first attack in the hope that the only stone has passed and that no more may develop. After every fresh attack spontaneous cure becomes more and more improbable, because common duct stones inevitably and often rapidly increase in size, and become naturally more difficult to pass through the duodenal orifice of the duct, which is only one-twelfth of an inch in diameter. Moreover, more or less septic infection of the ducts and liver frequently follows and leads to serious loss of liver function, with marked increase of the mortality after delayed operation.

Treatment.

MEDICAL.[3]

Although medical treatment rarely if ever cures calculous obstruction of the common bile-duct, it is indispensable and invaluable in relieving biliary colic, which by common consent is one of the worst of all pains. Morphia and atropine soon give miraculous, if only temporary, relief, and are a godsend to patients who have for any reason to wait for a cure by operation. Antiseptic treatment of the biliary tract by hexamine, salicylates, and sulphates is also valuable as a preliminary preparation to operation. Glucose and hæmostatics are also valuable safeguards when the risk of cholæmia or of hæmorrhage are serious in late or neglected cases.

OPERATIVE.

After the most careful preparation of the patient, to make her safer for operation, the abdomen is rapidly explored through a right paramedian incision in the epigastrium, and after a general survey especial attention is given to the liver, biliary tract, and pancreas. Sometimes it is necessary to remove a septic appendix, and frequently it is necessary to deal with stones in the gall-bladder and cystic duct, but nothing is done until the bile-ducts have been carefully palpated for stone.

(1) *Supraduodenal choledochotomy.*—Any stone found in the lower part of the duct is backed into the supraduodenal part of the common duct, where it is fixed, by the left index-finger passed into the foramen of Winslow, until it is removed through a longitudinal incision in a bloodless part of the duct well above the duodenum. A large lead probe is then passed through the duct into the duodenum, and also into the right and left hepatic ducts. Great patience is required to find and to remove all the stones and debris from the ducts, which often have to be cleaned with strips of gauze passed up and down.

Whenever there is reasonable doubt about the presence of a stone in the common bile-duct, an opening must be made into the duct and the passage must be proved to be clear by passing the large probe through the papilla into the duodenum. It should never be forgotten that stones may be present in the common duct for years without causing either dilatation of the duct or jaundice. At my first cholecystectomy I overlooked a small faceted solitary stone in a normal looking common duct. There was no history of jaundice. There were 99 stones in the gall-bladder and cystic duct, and I thought I had done well for the patient; but she had repeated attacks of biliary colic without jaundice during the next four years, and then another operation was at last accepted and proved entirely and permanently successful.

(2) *Retroduodenal choledochotomy.*—When a stone in the second part of the common duct cannot be backed into the first part it has to be removed by incising the duct directly over the stone after dividing the posterior peritoneum to the right of the second part of the duodenum, mobilising the latter and turning it forwards and inwards. More bleeding often attends this operation and it is more difficult to explore all the ducts satisfactorily.

(3) *Transduodenal choledochotomy.*—In a few cases a stone cannot be dislodged by reasonable force from the lower end of the common bile-duct. Even the passing of the probe fails to push the stone through into the duodenum. Then the transduodenal operation is necessary and generally proves very successful. A longitudinal incision is made directly over the

ne through the anterior wall of the duodenum ; en the papilla or duct is incised over the stone, which removed, and the incision in the front wall of the odenum is very carefully closed in reverse without rrowing the bowel ; two layers of fine catgut tures are used and a peritoneal flap is brought up om the mesocolon and sewn over the wound. I ve never seen any leakage after this operation. ter every choledochotomy I insert a fine rubber be (No. 10 rubber catheter) into the common ct and fix it there with a fine catgut suture. Failure do this may lead to disastrous leakage of infected le into the peritoneum.

In one of my cases the lesser sac filled with bile, hich I had to evacuate and drain at a second opera- on. In another case closure of the duct by suture as followed by return of colic, due to organising ood clot within the duct, which required a second eration ten days later. I also insert a larger ibber tube in Morison's pouch ; this I remove after vo or three days. The catheter becomes loose and removed after a week or ten days, and the wound pidly closes without any leakage of bile for more an two or three days.

Prognosis.

Mortality.—In my 116 cases of choledochotomy e death-rate was 12 per cent. Graham and Cole [4] cord 42 cases with a mortality of 11·9 per cent. any of these cases are seen too late for the best sults to be obtained. The mortality ought not to above 5 per cent. if the patients come reasonably rly ; whereas it is as high as 35 per cent. in late ses with infective cholangitis and perhaps pancrea- tis. A mortality of 12 per cent. in these 116 cases mpares very unfavourably with that of 1·6 per cent. my concurrent 434 cases of cholecystectomy. ther bad and late cases, with suppuration in and bout the gall-bladder, were treated by cholecys- stomy. By a coincidence there were 116 of these ith a mortality of 18 per cent.

From these figures it will be seen that I found holedochotomy necessary in 116 out of 666 conse- utive cases of gall-stones operated upon by me. lany of the deaths were chiefly due to delay, and ould have been avoided by early cholecystectomy.

Ultimate results.—In my experience, recurrence f gall-stones after choledochotomy is very rare, lthough symptoms of cholangitis sometimes continue r recur. I have not yet seen true recurrence of all-stones after cholecystectomy, but I have ccasionally found stones in the common duct which ad been overlooked when the gall-bladder was emoved.

Illustrative Cases.

CHOLECYSTECTOMY AND CHOLEDOCHOTOMY.

CASE 1.—A lady, aged 57, gave a history of five attacks f biliary colic during 1913 and 1914. Afterwards she was ell for 14 years, but in 1927 the attacks returned and were t first diagnosed as pseudoangina. In 1928 there were hree more definite attacks. In February, 1930, she eveloped right-sided pleurisy. Five days later a typical nd severe attack of biliary colic developed. Meanwhile here was a loud rub over the lower half of the right lung. he patient was laid up for weeks, but gradually recovered. n June 3rd a very severe attack of typical biliary colic tarted at 8 P.M. ; an injection of gr. ¼ of morphia was given, ut the patient did not sleep all night and had several igors. Next day there was marked tenderness over the all-bladder, which was felt. There was no jaundice. The emperature was raised and remittent for five days. holecystectomy was advised but the patient preferred o wait. She was ill for some weeks with irregular fever nd rheumatism in the shoulders and hands. She lost a tone in weight.

When I saw her for the first time in July, 1930, the liver was somewhat enlarged and the gall-bladder was palpable and tender. There was a moderate degree of jaundice.

Operation, July 17th. Kocher incision. The appendix appeared normal and was left alone, especially as there were stones in the common bile-duct as well as in the gall-bladder, and the patient was very ill. The stomach and duodenum were normal. The gall-bladder was chronically inflamed, thick-walled and shortened, drawing the front edge of the liver downwards and backwards, kinking it. The gall-bladder was very adherent to the front of the duodenum ; the adhesions were divided and tied. The common bile-duct was opened above the duodenum and 15 stones were removed from it and the common hepatic duct, a mass of them being impacted in the latter ; they were all made of cholesterin ; three were withdrawn from the common bile-duct low down, and some from the hepatic ducts. The large probe and scoop were passed through the papilla into the duodenum to dilate the orifice thoroughly. The gall-bladder was very adherent and embedded in the liver ; its fundus was shelled out, but a diverticulum extending downwards along the common bile-duct was so very adherent that some of it was left behind because of the danger to the main duct. In all, about 100 stones were removed. A tube was sewn into the common duct, and another large tube drained the kidney pouch. The operation lasted 1 hour and 20 minutes ; the patient stood it well and made a slow but complete recovery. She has remained quite well now for over 18 months.

CASE 2.—A man, aged 65, was sent to me in July, 1927. He had had severe kyphosis of the spine since the age of 20, when he was laid on his back for three years. When he was 30 he passed six gall-stones after suffering much from biliary colic. After this he was well for years, but the symptoms returned in 1922, when cholecystostomy was performed and 16 stones were removed from the gall-bladder. A fæcal fistula followed for some weeks and he was very ill. The symptoms returned a year later with more severe colic, dyspnœa, and præcordial pain resembling angina pectoris. I advised operation, but the patient waited until he became worse and jaundice had developed in March, 1929. An operation was performed during a remission. He was a tall, thin man, suffering from bad, rigid spinal curvature, so that his liver was drawn high up into the chest, and was very difficult of access.

Operation, April 10th. Kocher incision ; large ventral hernia ; a mass of dense adhesions in the right hypochondrium. With difficulty these were separated and the duodenum and stomach and liver identified. A small fibroid gall-bladder containing small calculi was found and used as a tractor, and thus the common bile-duct was traced ; it was dilated and thick-walled. No stone could be felt in it until it was opened, when a large amount of pale bile containing debris of stone escaped. On passing the index-finger down, a small stone was felt low down and was removed with the greatest difficulty by the supraduodenal route. A large lead probe was passed through the duct into the duodenum. The stone, which was a little larger than a pea, had been impacted at the duodenal papilla The operation took a long time—about one and a half hours—and the patient lost a good deal of blood, but his pulse was good at the end of the operation. He made a slow but complete recovery and has remained well for nearly three years.

Conclusions.

Infective inflammation of the gall-bladder is very common, and is difficult to cure medically. It often causes gall-stones, and sometimes cancer, to form in the gall-bladder or bile-ducts.

Timely radical operation has a low mortality, and offers a very good chance of cure. Delay often leads to serious and dangerous consequences. The results of operations upon the gall-bladder and bile-ducts are extremely satisfactory, and compare favourably with those obtained in any other branch of surgery. They will become still more satisfactory and even safer when patients come for operation before serious consequences, such as jaundice and suppuration, have developed.

INCREASED CARBOHYDRATE IN THE TREATMENT OF DIABETES MELLITUS.

By S. C. Dyke, D.M. Oxf., M.R.C.P. Lond.,
CONSULTING PATHOLOGIST, THE ROYAL HOSPITAL, WOLVERHAMPTON.

(*From the Diabetic Clinic of the Hospital.*)

THE vast improvement in the treatment of diabetes is one of the most striking features of the last decade in medicine; this improvement is frequently attributed entirely to the introduction of insulin, and assuredly insulin has been the means of saving innumerable lives and of restoring to full health and vigour many who but for it would have had to look forward to a short life of invalidism and semi-starvation. Even before the introduction of insulin, however, F. N. Allan, who may be regarded as the father of the modern treatment of diabetes, had laid down the general principles which, even without the discovery of insulin, would have revolutionised the management of diabetes and which actually constitute the basis of present-day treatment.

By removing variable proportions of the pancreas of dogs, Allan and his co-workers produced diabetes of varying severity. In a mild case thus experimentally produced they found that, by careful dieting and by keeping the animal in a state of under-nutrition, it was possible to hold the diabetic condition in check. If, however, the animal thus brought to equilibrium were permitted to eat all the food it fancied, the experimentally produced diabetes progressed rapidly to a fatal issue. Given just sufficient islet tissue to deal with the minimal glucose requirements of the animal and presented with that minimum only, the pancreas would carry on; faced with more glucose than it could deal with, the islet tissue rapidly degenerated, and a frank diabetic condition supervened and progressed rapidly to a fatal issue.

Thus was developed the principle of pancreatic rest; islet tissue only just up to requirements may serve its owner so long as it is not overworked; overwork it and it will collapse altogether. Before the introduction of insulin the only known means of inducing pancreatic rest was starvation or under-nutrition. The degree to which these can be pushed is limited and it is, on the face of it, undesirable to starve an already wasted subject; moreover, even in the healthy subject starvation leads to the breakdown of stored fat and rapidly gives rise to ketosis with its attendant evils. None the less, starvation is a valuable means of resting the pancreas; by means of preliminary starvation and thereafter a diet below the actual metabolic requirements it was possible, even before the days of insulin, to retain in reasonable health, albeit in a state of subnormal vigour, numbers of diabetics who would otherwise have early succumbed to their disorder.

Starvation in the treatment of diabetes is not now necessary nor is under-nutrition actually desirable. By means of the judicious use of insulin it is possible to rest the pancreas without recourse to either of these measures. In the past the value of insulin in this respect has not been sufficiently realised. By the time that insulin was introduced, the general dietetic principles of Allan had been so firmly established that insulin was used merely as an adjunct to the dietetic treatment. Preliminary starvation was enforced until the blood-sugar became normal, and the diet was then slowly stepped up until it became evident that the carbohydrate tolerance had been reached. At this stage, and not before, insulin introduced into the treatment. There was and is a general feeling that once insulin has been intr duced into the management of a case its use mus be maintained throughout life. This is far fror being so. The early and free use of insulin as means of securing pancreatic rest brings the cas under control quickly and easily and without dange of ketosis; in the milder cases its use may be droppe as the glucose tolerance increases; in all cases th size of the dose necessary at the commencement treatment always greatly exceeds that on which th case finally becomes stabilised. The use of insul tends to reduce ketosis; starvation to produce i On these grounds alone it is preferable to secu pancreatic rest by means of insulin rather than b starvation.

INSULIN TO REDUCE THE LOAD ON THE PANCREAS.

Simple rest, however, does not constitute th whole of the treatment of diabetes; the pancrea rested, and with some of its function restored, mu not thereafter be overworked; it is as a means taking some of the load from the pancreatic isl tissue that insulin has been almost solely used the past, and its importance in this direction remai undiminished. In the past, however, there h undoubtedly been a failure to take full advantage the possibilities offered by insulin in this respect.

The diets in use as a result of the work of All at the time of the introduction of insulin most allowed carbohydrate, protein, and fat in the appro mate proportions of 50, 50, and 150. So long as diet conformed to Woodyate's formula that F shou not exceed 2C plus ½P it was considered that k would not develop, and in many instances pa did well on such diets either with or without insuli in fact, so enormous was the improvement over previous forms of treatment that for a time it [illegible] that nothing better could be found. As, howe the potency of insulin was fully realised, there w questioning as to whether the low-carbc [illegible] fat diets introduced as a result of Allan's work we really the best that could be devised, and the [illegible] the inquiry is pushed the more evident it becom that they are not.

Allan's original work on dogs was done [illegible] insulin; he realised that excess of fat in the [illegible] tended to some extent to reduce the tolerance f glucose, but fat in large amounts had to be inclu in the diet because it offered the only means providing the necessary calories above those [illegible] available by the metabolism of glucose, and of [illegible] the amount, whether elaborated from carboh [illegible] or protein, had to be strictly limited. On clinic grounds it has now become evident that with t intelligent use of insulin strict limitation of carb hydrate is neither necessary nor desirable. It is matter of experience that on adequate insulin dosa the patient who is not slavishly observant of his di often does rather better than the one who adher strictly to the letter of the doctor's word. Patien on a diet just conforming to Woodyate's formula many instances show a tendency to develop son degree of ketosis—and no diabetic can be regard as satisfactorily under control who shows acetone the urine. More free-and-easy patients who exce their diet in moderation—and when this is the ca it is practically always to the carbohydrate ratio that the addition is made—may escape acetonur even though some degree of glycosuria develop, an it is a matter of common observation that the diabet with a little sugar in the urine feels and actually is er health than his fellow who is free of glycosuria has acetonuria.

hese considerations have led within the last few rs to a considerable increase in the carbohydrate decrease in the fat ration of the diabetic. Ever e the introduction of insulin it has been recognised t by its use in sufficient amount it is possible to ance almost any amount of carbohydrate in the betic diet. It was, however, widely assumed that increase in the carbohydrate of the diet would essitate a proportional increase in the insulin age, and the average *patient greatly prefers* to up with a low carbohydrate intake rather than increase the bulk and the number of his daily lin injections. Experience has shown that the mption that increase in carbohydrate necessitates roportional increase in insulin dosage is entirely e. It has been widely held that one unit of lin may be regarded as approximately sufficient bring about the metabolism of one gramme of ose, and within very wide limits this is *true* ugh for the first 15 or 20 units of the dosage. reafter, however, it is found that increasingly e amounts of carbohydrate may be added to diet with only relatively small increase in the lin dosage. Thus, after the first 15 or 20 units of lin, a further 10 may be sufficient to enable the ent to deal with another 30 g. of carbohydrate, the addition of a further 30 g. of carbohydrate the diet may only necessitate a further 5 or 10 ts of insulin.

aking advantage of these facts, it is possible to duce almost any desired amount of carbohydrate the diet and to diminish the fats accordingly. merica, where meat-eating is apparently regarded something of a crime and where carbohydrates to bulk more largely in the diet than they do in country, recognition of these possibilities has the inclusion *of very large amounts*—up to 300 350 g.—of carbohydrate in the diabetic diet. certain cases, particularly in growing children, a régime has had very striking results. It is erally admitted, however, that with such diets insulin requirements are what would be regarded large in this country. A dosage of 100 units daily not unusual, and more frequent dosage is necessary. ghly concentrated insulin is more generally available America than in this country, so that the actual lk of insulin required on these very high carbodrate diets is not excessive; the frequency of osage, to which the American patient apparently oes not take exception, constitutes in this country distinct objection. None the less there undoubtedly re cases, particularly in children, in which very igh carbohydrate diets may be used with distinct dvantage.

In this country the average patient is happy on a carbohydrate intake considerably below *300 g.* Amounts of from 150 to 250 g. will satisfy most individuals, and *by the judicious use of insulin* these may readily be included in the diabetic diet.

THE REGIMEN OF THE HIGH CARBOHYDRATE DIET.

In the treatment of a case with higher carbohydrate diet, insulin must be used freely in the early stages; one hundred or more units per day may be required and the doses may have to be given four times in the twenty-four hours—even more frequently if there is any danger of coma. At the onset of treatment, no matter what the state of the patient, the carbohydrate content of the diet should be at least *100 g.*; *if the general condition is* bad this may be given in the form of glucose solution flavoured with fruit juice. If insulin be used boldly and freely in the early stages of treatment, there need be no fear but that it will be possible very considerably to decrease the dose as improvement occurs. It is the aim of the writer, no matter what the size or frequency of the initial insulin dosage, ultimately to reduce it to one dose daily, to be taken in the morning. In many cases this becomes possible, but only when the insulin requirement is at or below 40 units daily. Once brought under control, many patients may be kept so on a single morning dose of insulin of up to 40 units; some patients, however, will not even tolerate this as their single daily dose, and I have never had a patient whom it was possible to keep under control on a single daily dose larger than this. Where the daily insulin requirement is less than 40 units it is usually quite feasible to concentrate the whole of this in the single morning dose, even though the diet contain up to 150 g. of carbohydrate. In such cases it is frequently desirable to arrange the diet so that the patient takes from 10 to 15 g. of carbohydrate in the middle of the morning; this may be taken as half a pint of milk, an ounce slice of bread or four ounces of fruit—all roughly equivalent in carbohydrate content.

In the management of the case it is important to ascertain early in treatment whether the weight of the patient be normal for his age and height. The normals may readily be ascertained from a height-age table. If the weight be above normal, steps must be taken to reduce it, and this may be a matter of some difficulty; to increase it is infinitely easier, but in any case the establishment of the particular diet and insulin dosage optional for any given case is not an easy matter. It is difficult—in fact almost impossible—to carry out treatment in the early stages satisfactorily except in an institution, and every effort should be made to get the diabetic, even the *relatively mild* case, into some place where the diet can be carefully regulated, the weight followed, and frequent determinations of the blood-sugar made.

Treatment is better commenced in bed. Roughly speaking, the average adult at rest requires *from* 1000 to 1200 calories daily, and if not overweight the patient may be prescribed a diet providing this amount and containing approximately 100 g. of carbohydrate. Of protein 1 g. per two pounds of body-weight may be allowed, the remainder of the diet being made up of fat. If the patient be above weight the same carbohydrate and protein content is prescribed, but the fat ration is reduced as deemed advisable.

If on admission the blood-sugar is found to be high, insulin is given at once and freely, and the same applies if the blood-sugar rises on the diet. Roughly speaking, if the blood-sugar at the commencement of treatment be above 0·3 per cent., insulin may be started with a morning dose of about 40, a midday dose of 10, and an evening dose of 20 units. As treatment proceeds it may become evident that much larger doses are necessary, and there should not be the least hesitation about giving them, the *morning* dose always being kept the largest and the midday the smallest. Not until the blood-sugar is consistently within normal limits and the urine free of sugar is the diet increased. It is then raised to approximately 2000 calories with a carbohydrate content of from 125 to 150 g. At this stage the patient will commence to show evidence of hypoglycæmia after some or all of the insulin doses. This is a good sign; a few lumps of sugar are kept by the bedside and the patient is instructed to take one at the onset of symptoms with the nature of

The animals were killed from 50 to 113 days after inoculation. The average length of life after infection was 83 days. In obtaining the blood, in culturing in veal broth tubes, and in the technique of making and staining the films, Dreyer and Vollum's method has been followed.

About 0·5 c.cm. of blood taken immediately after death was run into veal broth culture tubes containing 10 c.cm. of medium, and incubated for one to two months. With *a platinum spade, part of the clot was detached, spread* in a thick film, stained by Ziehl-Neelsen, being counterstained with picric acid and the decolorisation assisted by washing with equal parts of acetone and alcohol.

Sixty-three guinea-pigs suffering from glandular and generalised tuberculosis have been examined. Twelve of the animals had been inoculated with a laboratory strain of tubercle bacillus, and had received injections of tuberculin. In one of these cultures typical acid-fast bacilli were found growing luxuriantly in the blood clot and in the broth; a leptothrix was also present as a contamination. The remaining 51 animals had been inoculated with fresh human pathological material; the strain therefore had not previously been subjected to artificial culture. No growth of bacilli was found in films, but isolated bacilli were found in four; in none of these was more than five possible bacilli found, after searching for one to two hours.

From 27 of these veal broth tubes subculture was attempted by spreading a portion of the clot on to Dorset's egg slopes. These were incubated for 2 to 3 months, the cultures being filmed after 6 to 12 weeks. In two slopes slow growth of tubercle bacilli was found to have taken place on microscopic examination after 2½ months. A few other blood cultures were rejected on account of contaminations, and are not included in this series. Thus from the 63 guinea-pigs three cultures of tubercle bacilli have been obtained. It is suggested that my failure to obtain results comparable to those of Dreyer and Vollum may be due to my having used diverse infecting strains instead of stock strains from the laboratory.

ANIMAL INOCULATION.

The most reliable method of demonstrating the presence of a small number of tubercle bacilli in a bulky material is generally considered to be by animal inoculation; though it is a question whether, if the bacilli be very few, they may not fail to cause infection. Striking variations have been reported in the frequency with which the demonstration of tubercle bacilli from the blood stream can be effected by the method of guinea-pig inoculation.[9] Except in cases of generalised miliary tuberculosis, results have often not been consistent with our general conception of the probable presence of bacilli in the blood stream during tuberculous infection. Thus, Distaso, working in this laboratory in 1921, found negative results in cases of pulmonary tuberculosis with pyrexia, and in surgical tuberculosis, while from 13 patients with chronic ambulatory afebrile phthisis, nine of the inoculated guinea-pigs developed tuberculous lesions and two others doubtful lesions.[10]

In this series inoculations have been made from 16 patients, from 4 to 10 c.cm. of blood from an arm vein being added to an oxalate tube, and injected intraperitoneally into guinea-pigs as soon as practicable. In some cases this was followed by the formation of a slough, at the site of inoculation, which healed in due course. One animal died ten days after inoculation; no macroscopic changes were detected post mortem, and it must be assumed that death was due to a late toxic effect of the blood absorption.

The cases were chosen from their clinical [illegible] pect being most likely to show the dissemination [illegible] f tuber[illegible] bacilli by the blood stream. The remaining 15 cas can be grouped thus:—

Group I.—Five cases of extensive bilateral pulmona tuberculosis, all doing badly, two being in the last stages the disease; one suffering from a dactylitis in additio and another from a tuberculous eye condition.

Group II.—Four cases of acu[illegible]e phthisis, of more rece *origin, rapidly becoming worse.*

Group III.—Three cases of chronic pulmonary tuberculos suffering from metastatic joint disease.

Group IV.—Three cases of "surgical" joint tuberculos In these cases the blood was centrifuged, the plasma bei used for other investigations and the red cell deposit bei inoculated.

Of the guinea-pigs from Group I. [illegible] case s, [illegible] after 12 weeks; post-mortem examination [illegible] no lesions to account for the death. Three [illegible] well, and were killed after 9 weeks, 10½ [illegible] weeks respectively; thorough post-mortem examination showed no lesions. One guinea-pig, which received 8 c.cm. of blood from a male case of ad[illegible] pulmonary tuberculosis of two years' st[illegible] developed enlargement of the inguinal glands. [illegible] was killed nine weeks after inoculation, and present[illegible] caseating glandular tuberculosis of inguinal, abdomin[illegible] and tracheo-bronchial glands with tubercles in th[illegible] the spleen and scattered miliary tube[illegible] in th[illegible] lungs. Acid-fast bacilli were demonst[illegible] cells [illegible] ed by [illegible] of 3 [illegible] caseous glands; and afterwards by cultures [illegible] ed aft

The guinea-pigs from Group II. were [illegible] ectivel 9 weeks, 10½ weeks, 19 and 26 weeks [illegible] Post mortem there was no evidence of [illegible] rculosi [illegible] necrot The animal surviving for 26 weeks had an [illegible] of whic polymorphonuclear abscess of the splee[illegible] faile histological and bacteriological investig[illegible] to reveal the cause.

The three animals from Group III. were [illegible] ectively 19 weeks, 26 weeks, and 26 weeks re[illegible] illed aft two of the animals from Group IV. were

12½ weeks and 11½ months respectively. All were carefully examined post mortem, and no evidence was found of tuberculosis. The other guinea-pig from Group IV. showed no evidence of infection after three months, the glands were normal and the weight increasing; it was considered negative, and was utilised for another purpose. The details are set out in the Table.

SUMMARY.

1. On the principle of Löwenstein's technique, cultures were made from the heart blood of 40 tuberculous guinea-pigs. Acid-fast bacilli failed to grow.

2. From 30 sanatorium cases of pulmonary tuberculosis, blood clot was digested with pepsin by the method of Jousset; after sterilisation with acid, cultures of the residue on egg medium failed to grow tubercle bacilli.

3. From small quantities (0·5 c.cm.) of heart blood of 63 tuberculous guinea-pigs cultured in veal broth by the method of Dreyer and Vollum, one primary positive culture was obtained, and in two cases subcultures on egg medium were successful.

4. Blood from 15 tuberculous patients has been injected into guinea-pigs. One animal, inoculated from a case of advanced pulmonary tuberculosis, developed glandular and generalised tuberculosis. The other 14 proved negative.

I am indebted to the Medical Research Council for a part-time grant, I wish to thank Dr. W. Davies and Dr. A. Brownlie for allowing me access to their cases; Prof. G. Dreyer and Mr. R. L. Vollum, Ph.D., for a personal interview; and Prof. S. Lyle Cummins and Dr. W. H. Tytler for help and advice.

THE CULTIVATION OF THE TUBERCLE BACILLUS

AND THE OCCURRENCE OF TUBERCULOUS BACILLÆMIA.

BY JOHN N. CUMINGS, M.D., M.R.C.P. LOND.,
ASSISTANT PATHOLOGIST, KING'S COLLEGE HOSPITAL.

THERE has always been difficulty in obtaining a primary growth of the tubercle bacillus from pathological materials, such as sputum, pus, and urine. Corper[1] described a potato medium, on which he claimed to be able to grow the tubercle bacillus with some degree of ease, about five weeks elapsing before the appearance of visible growth, and Corper and Uyi[2] reported successful results with the same medium Cunningham and Cummings,[3] using this medium have obtained 14·8 per cent. more positive cultures than positive direct smears. I have used this medium since its introduction, and also more recently that used by Huth and Lieberthal[4]—the Hohn egg medium.

In the investigations described below, the following minor alterations and additions have been made in technique.

In using Corper's medium, the wool plugs are always waxed with paraffin to prevent evaporation and subsequent drying of the medium. In the preparation of the egg medium one sterile flask, roughly graduated, is used throughout; and the tubes are covered with rubber caps instead of waxing. With both methods sulphuric acid is used to kill organisms other than the tubercle bacillus; the strength may be between 5 per cent. and 15 per cent., but 15 per cent. acid must be used when dealing with fæces. After 30 minutes' sulphuric acid treatment, either at room temperature or at 37° C., the emulsion is centrifuged and the deposit very carefully washed with sterile normal saline and recentrifuged before the medium is inoculated with the deposit. It was found experimentally that if the saline washing is omitted the tubercle bacillus will only grow very slowly after contact with 15 per cent. and 10 per cent. sulphuric acid; and even after contact with 6 per cent. and 5 per cent. sulphuric acid, growth is not so rapid as when careful washing is adopted.

THE POTATO MEDIUM.

The efficiency of the potato medium was tested on 66 specimens, four tubes being inoculated from each specimen. In 35 of the 66 specimens tubercle bacilli had been found in direct smears, and a further 11 specimens were proved tuberculous by guinea-pig inoculation. None of the 20 specimens which gave negative results in direct smears and in the guinea-pig gave positive results in culture. Of the 11 specimens which were negative in direct smears but positive in the guinea-pig, only one gave a successful culture; with two others the cultures were spoilt by early growth of contaminants, and the remaining eight cultures were sterile. Of the 35 specimens positive in direct smears, 7 gave successful cultures; with 10 the cultures were spoilt by contaminants; and the cultures of 18 remained sterile. From a total of 46 specimens proved by other methods to contain tubercle bacilli, successful cultures were obtained with 8; and tubercle bacilli were never isolated in culture when other methods had failed. Subcultures on the potato medium were uniformly successful, growth appearing between the tenth and seventeenth days. Details of the specimens giving successful cultures are shown in Table I.

TABLE I.

Case.	Material.	No. of days for growth to appear.	Direct smears.	Case.	Material.	No. of days for growth to appear.	Direct smears.
1	Sputum.	66	+	5	Sputum.	51	+
2	Urine.	55	+	6	Sputum.	27	+
3	Sputum.	30	+	7	R. ureteric urine.	41	+
4	Pus.	57	+	8	Pus.	44	–

In specimen 8 in which no bacilli were found in direct smears, a guinea-pig inoculated with the same material died with tuberculous lesions four days before growth was detected on Corper's medium, though the egg medium (Case 1) had shown growth three weeks earlier.

THE EGG MEDIUM.

The efficiency of the egg medium was tested on 34 specimens, four tubes being inoculated from each specimen. In 17 of these specimens, tubercle bacilli had been found in direct smears, and a further seven specimens were proved to be tuberculous by other methods. None of the 10 specimens which gave negative results in direct smears and in the guinea-pig gave positive results in culture. Of the 7 specimens proved to be tuberculous by methods other than direct smear examination, 4 gave positive cultures and 3 were sterile. Of the 17 specimens positive in direct smears, 8 gave successful cultures, 3 cultures were spoilt by contaminants, and 6 remained sterile. From a total of 24 specimens proved to be tuberculous, successful cultures were obtained in 12; and tubercle bacilli were never isolated in culture when other methods had failed. Subcultures on the egg medium were uniformly successful, growth appearing between the seventh and tenth days. Details of the specimens giving successful cultures are shown in Table II.

TABLE II.

Case.	Material.	No. of days for growth to appear.	Direct smears.	Case.	Material.	No. of days for growth to appear.	Direct smears.
1	Pus.	23	—	7	Sputum.	23	+
2	Pus.	53	+	8	Pus.	35	+
3	Sputum.	31	+	9	Pus.	25	+
4	Sputum.	30	+	10	Urine.	28	—
5	R. ureteric urine.	41	+	11	Pus.	68	—
6	Sputum.	41	+	12	Pus.	18	—

With this medium all the specimens in which cultures failed to give any growth despite presence of bacilli in direct smears were sputum specimens. Uniformly successful cultural results were obtained with positive pus and urine specimens in the absence of contamination.

At times over the surface of the medium, especially at the lower end of the slope, will be seen a reddish-coloured growth, which will be found to be composed of bacilli, resembling the tubercle bacillus but somewhat thicker. These organisms are not alcohol-fast, although at times some of them may be acid-fast. This growth may be obtained in uninoculated tubes, and may only appear if the tubes are kept at room temperature for two or three days and then incubated. The bacillus is easily distinguishable from the tubercle bacillus. It is suggested that before use on the day following the preparation of the medium the slopes should be heated to 70° C. for half an hour. In practice this procedure has been found very satisfactory.

BLOOD CULTURE.

Löwenstein [5] has succeeded in culturing the tubercle bacillus from the blood of patients with tuberculous lesions and also from patients with other diseases, such as disseminated sclerosis, using a special egg medium. I have similarly attempted blood culture using the following techniques: Löwenstein uses citrated blood and acetic acid, and I have followed this practice, but have always used the sulphuric acid treatment, as for sputum, before inoculating Hohn's egg medium. I have also treated a similar quantity (10–12 c.cm.) of citrated blood after centrifugalisation with sterile distilled water instead of the acetic acid. I have found this latter method superior to the other, in that there is less final deposit, as in every case all the deposit is used in inoculating the medium. It was also found that in the control experiments (see below) the deposit obtained by this latter method always grew a few days before the former.

The efficiency of the egg medium for blood culture was first tested by mixing some tuberculous sputum—shown by direct smears to contain tubercle bacilli—with blood from a healthy adult, and treating the whole in exactly the same manner as the blood alone would have been treated. Growths of tubercle bacilli were obtained, and in one case actually some few days before growth had taken place from the sputum alone. Similarly tubercle bacilli from a primary culture were added to blood, and treated as above, and all yielded positive cultures.

In all 25 blood cultures from different individuals have been performed and not one positive culture has been obtained. Of these 25 cases, 15 were from patients with tuberculous lesions. There were 11 cases of pulmonary tuberculosis, one of miliary tuberculosis, one of renal tuberculosis, one patient with Pott's disease, and one with tuberculous meningitis. The other 10 comprised eight cases of disseminated sclerosis and two of lymphadenoma. The diagnosis of all these cases was established as definitely as possible by pathological as well as by clinical investigations. Microscopic as well as macroscopic examination was performed before a culture was pronounced positive or negative; and all cultures were kept at least three months, some even being kept five months before being pronounced negative.

Löwenstein [5] obtained 148 positive blood cultures from 304 tuberculous patients, whereas I have not obtained one positive result on a medium which under the conditions of my control experiments was found to be efficient and which also gave some 50 per cent. positive results from other pathological materials. Neither have other diseases yielded any positive cultures, although Löwenstein [5] [6] obtained growths of tubercle bacilli from such conditions as disseminated sclerosis (17 out of 40 cases) and rheumatism (21 out of 21 cases). Dreyer and Vollum [7] have cultured blood from guinea-pigs dying with tuberculous lesions and have obtained positive results in 91·4 per cent. of cases. Bingold [8] obtained three positive blood cultures from 4[illegible] cases; Jontofsohn [9] obtained three positive results from 41 cases of lung tuberculosis and nine cases of surgical tuberculosis, and Moos Schwabacher [10] obtained one positive result from a case of pulmonary tuberculosis. Muggia [11] obtained negative results in four cases of pulmonary tuberculosis and five cases of acute rheumatism; and Favero [12] similarly obtained negative results from 40 cases; he also controlled his cultures with guinea-pig inoculations, all of which were also negative.

SUMMARY.

Attempts to cultivate the tubercle bacillus from pathological materials on Corper's potato medium and Hohn's egg medium are described. The egg medium yielded more than twice as many positive cultures as the potato medium, and a positive culture has only been obtained in about 50 per cent. of cases in which the tubercle bacillus was demonstrated by direct examination or guinea-pig inoculation.

Blood culture was performed in cases of tuberculosis, disseminated sclerosis, and lymphadenoma, and in no case was a positive result obtained.

I wish to thank Dr. E. ff. Creed for his continued assistance, and also the staff of King's College Hospital for allowing me to make use of their cases.

CLINICAL AND LABORATORY NOTES

SIMULTANEOUS DISAPPEARANCE OF GALLOP RHYTHM AND BUNDLE BRANCH BLOCK.

BY MAURICE CAMPBELL, M.D. OXF., F.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO GUY'S HOSPITAL; PHYSICIAN TO OUT-PATIENTS, NATIONAL HOSPITAL FOR DISEASES OF THE HEART;

AND

S. S. SUZMAN, M.R.C.P. LOND.,
CLINICAL ASSISTANT, CARDIOGRAPHIC DEPARTMENT, GUY'S HOSPITAL, AND NATIONAL HOSPITAL FOR DISEASES OF THE HEART.

THE following case is interesting and unusual, for at first it illustrated the association of gallop rhythm with bundle branch block, and later the disappearance of both of these at the same time—suggesting that the gallop rhythm was due to the bundle branch block.

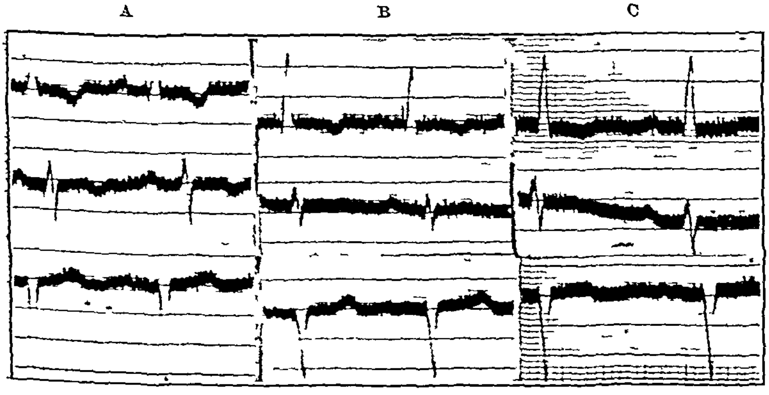
The patient had syphilis when aged 25, and was thoroughly treated with mercury and iodides. He married two years later and had five children, who were apparently healthy, and three who died young, these not being the three eldest. He was a heavy smoker and drinker, admitting to 8 pints of beer daily and 4 oz of tobacco a week. In spite of this he made a good recovery from pneumonia at the age of 41.

At 50 he took to easier work as a caretaker: he had already started to put on weight and to be a little short of breath Six months later while in bed he vomited a large amount of dark congealed blood. This was attributed to cirrhosis of the liver, and he reduced his consumption of alcohol very considerably.

He was first seen by us in May, 1931, when he was 52 During the previous two years he had increased in weight from 11½ st. to 13 st., and had become short of breath on exertion. During the previous six weeks he had begun to complain of attacks of pain represented by a choking feeling in the throat, when he had to take off his tie and collar. In one attack in bed he awoke with a choking sensation and felt he was going to die Two attacks, one while in bed and one while walking, were specially severe.

On examination his heart was much enlarged, mainly to the left (orthodiagram 17 cm), and the aorta was considerably dilated without any local aneurysm; his blood pressure was 210/130; the aortic second sound was not clear, but there were no murmurs. He had well-marked gallop rhythm, and a flick could be felt on palpation at the apex corresponding to the third sound of his gallop rhythm. An electrocardiogram showed typical right bundle branch block. His Wassermann reaction was negative. He was seen again several times, the gallop rhythm remaining unchanged; the electrocardiogram on two occasions showed no difference in the degree of bundle branch block (Fig. 1, A and B) He was given iodides, but not in large doses.

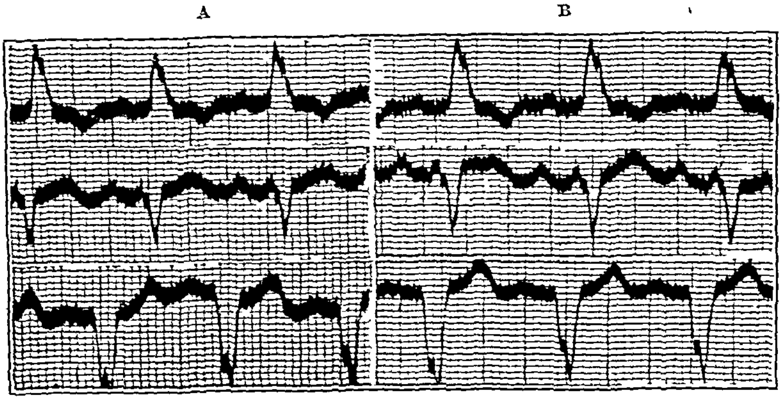
FIG. 2.



On July 10th, the gallop rhythm persisting unchanged, he was allowed to start work, for this was extremely light with no physical exertion, and he felt that otherwise he might lose his position altogether. His blood pressure was 190/120. He only managed to work for nine days, and then had an attack of orthopnœa at night with the choking feeling lasting most of the time for eight hours He sweated a lot, and again thought he was going to die.

In spite of this, when he came to hospital on August 7th gallop rhythm was not noticed, the flick was not felt on palpation over the apex, and, to our surprise, the electrocardiogram showed no bundle branch block, there being only left ventricular preponderance with the T wave inverted in lead I. and slightly inverted in lead II. (Fig 2, A). His blood pressure was 180/130.

FIG. 1.



He returned to work in September, and when next seen had been at work a month. He felt better and was able to walk a mile with less dyspnœa. There was no gallop rhythm, and his electrocardiogram was similar to that in August, but T I. was less deeply inverted, and T II. was flat (Fig. 2, B)

In December, and in February, 1932, nine months after he was first seen, he was at work and was again rather better, though he had been in bed once for a few days with a slight recurrence of pain. The first sound was almost clear; there was no gallop rhythm, and no bundle branch block in the electrocardiogram; the T wave in lead I. was again better, and now only just inverted (Fig. 2, C) There was no significant change in his orthodiagram, and the blood pressure on the last three occasions had been 190/130, 210/130, and 220/125.

Bundle branch block has often been given as one cause of gallop rhythm, but we are not aware of any case where the disappearance of gallop rhythm has been found with a change from bundle branch block to normal conduction. In this case the note about the disappearance of gallop rhythm was made before his electrocardiogram was taken. It is possible that the whole history represents a small coronary thrombosis in a patient with high blood pressure, the bundle branch block and gallop rhythm being a temporary result of this, but the clinical history is not at all suggestive of this. The subsequent changes in the T wave in lead I. would certainly support this view, but it was not the original diagnosis, and we had assumed that he was a patient with permanent sclerotic changes in the heart, and that his bundle branch lesion was likely to be permanent.

A CASE OF PORTAL CIRRHOSIS.

BY JOHN H. ANDERSON, C.M.G., C.B.E., M.D. MELB.,
PHYSICIAN, RUTHIN CASTLE.

A medical man, aged 47, had lived for a long time in the East. He was known from boyhood for his abnormally large appetite, being fond of highly spiced and seasoned foods; he was a heavy beer-drinker as a student, he drank a good deal of whisky during the war, and for the last three years he had been "doing two men's work and taking stimulants to keep going." From 1927–1929 he had chronic infection of frontal sinuses and antra and in October, 1929, had an acute attack of frontal sinusitis, culminating in spontaneous discharge of pus (*Staphylococcus aureus* on culture); there had been similar attacks of varying severity every 10 to 12 weeks since. Lately these attacks had been accompanied by increasing colic and tympanites, finally requiring morphia. About the middle of April, 1931, he noticed slowly increasing abdominal distension and in June tapped himself and withdrew 22 pints of normal ascitic fluid; the self-tapping was regularly repeated at five to seven days interval. A big hæmatemesis followed third tapping and a smaller one two days later. He lost 2½ st. in weight, and on admission to hospital complained of distension and a constant dull abdominal ache, most marked over liver, only relieved by tapping.

Examination.—Colour poor, emaciated, weight 8 st. 9 lb. (normal 11 st.). Circulatory system: B.P. 130/100, pulse 100, heart sounds clear. Blood: Hb. 75 per cent., red cells 4,100,000, and white cells 11,600 per c.cm.; differential count, polymorphonuclear leucocytosis; W.R. negative; blood-sugar, non-protein nitrogen, cholesterol, icteric index and van den Bergh reaction normal; blood sedimentation rate greatly increased at 130 mm. per hour. Nervous system normal. Respiratory system normal except for scattered moist sounds both bases. Alimentary system: tongue coated. Abdomen: distended with fluid, marked thrill; liver palpable, not tender, no nodules felt. Urine: normal except for trace of bile-salts occasionally. Fæces: occult blood present, occasional mucus; culture negative; no amœbæ seen. X ray examination: head sinuses clear. Barium meal: duodenal cap rigid and deformed, bowel as a whole shows evidence of outside pressure.

Diagnosis.—Cirrhosis of liver with perihepatitis and possible mild colitis.

Progress.—Gradually downhill. Tapping necessary every five to seven days and yielded a normal ascitic fluid. Within a couple of hours of tapping a grating over the liver could be heard and felt which disappeared as the fluid reaccumulated. Appetite improved and bowels acted copiously after tapping, the largest stool passed weighing over 26 oz. Leucocytosis increased to 18,000 and pain became peritoneal shortly before death, which took place four months after first tapping.

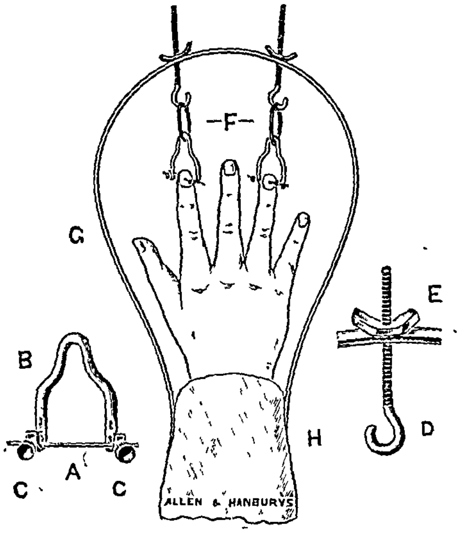
Post-mortem examination.—Liver small, tough, granular on section with a thickened capsule; pancreas firmer than usual; other organs fairly normal except for dilated veins at cardiac end of œsophagus.

Comments.—(1) A case of portal cirrhosis is briefly described in which the onset of severe symptoms came shortly after a repeated acute infection. (2) The action of alcohol per se in producing cirrhosis is debatable; it is suggested in this case that the detoxicating power of the liver was primarily weakened by alimentary excesses and bacterial poisoning. (3) Paracentesis was performed 22 times in all, 11 times by the patient himself and in such unlikely places as hotel bedrooms and bathrooms on board ship. (4) The amount of appetite and the size of the motions depended entirely on a mechanical factor, the intra-abdominal pressure. (5) Contrary to general custom, support for the abdomen by a binder, during and after tapping, was refused as it increased pain and discomfort.

NEW INVENTIONS

AN APPARATUS FOR THE TREATMENT OF FINGER FRACTURES BY SKELETAL TRACTION.

THE application of skeletal traction is now in common use for treating fractures of the long bones. The method is equally applicable to fractures and dislocations of phalanges of the hand and of the metacarpals, although it involves the use of some specialised apparatus. The illustration shows a simple and inexpensive method for applying traction to the fingers. The traction appliance consists of a short length of steel wire (A), which transfixes the terminal phalanx from front to back through the nail; rustless steel wire, 0·8 mm. thick, is suitable for the purpose. A straight needle can be employed instead of the wire, but on account of the temper of the metal there is a risk of breakage. The wire is held in a strut (B), which is made out of stout brass wire. Milled screws (C C) hold the wire firmly. The pull to be exerted in finger fractures is not great and so tensioning of the wire is unnecessary. The pull is exerted through the bracket (G), which is firmly held on to the forearm by a light plaster case (H). The bracket is conveniently made from an aluminium strip about 1·25 cm. × 0·5 cm. Holes are drilled in the bracket in suitable positions for the passage of the threaded hook (D). The position of this hook is controlled by butterfly nut (E). Steady traction is obtained by the interposition of a stout rubber band or section of a rubber tubing (F) between the hook and the strut (B). Such an appliance will pull out any recent fracture of a phalanx or metacarpal in which there is overlap, and is powerful enough to reduce a dislocation at the interphalangeal joints of some standing. In one case I was able to reduce a dislocation at the proximal interphalangeal joint which had been present for seven weeks.



The appliance has been made for me by Messrs. Allen and Hanburys, Ltd., Wigmore-street, London, W.

C. MAX PAGE, M.S.Lond., F.R.C.S. Eng.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE.

SECTION OF MEDICINE.

At a meeting of this section held on April 26th, the chair was taken by Dr. H. Morley Fletcher, the President, and Dr. S. H. Cookson read a paper on the size and shape of the

Heart in Thyroid Disease.

Opinion, he said, was much divided on whether the heart was or was not enlarged in disorders of the thyroid gland in which the secretion was excessive or abnormal. He would, however, show radiographs proving that the heart was often enlarged in goitre, and that it had a characteristic picture. This picture included: (1) convexity of the pulmonary arc instead of concavity—filling out of the pulmonary bay; (2) elevation of the aortic knob; (3) straightening of the left border, due to a combination of (1) with some enlargement to the left. In the result the heart became rather ham-shaped. In a girl of 16, with goitre symptoms of only two months' duration, the aortic knob was as high as the clavicle and the pulmonary bay convex, although there was no enlargement. Other young subjects showed these signs together with enlargement. In severe cases gross enlargement might be seen, but his series gave no support to the view that enlargement was mechanically produced by pressure of the goitre on the vessels. Radiographic evidences of heart failure were prominence of the superior vena cava, effusion at the right base, and congestion of the lung roots.

In mitral stenosis the pulmonary arc might be developed to an extreme degree and below it might be seen a second bulge, due to the conus arteriosis. Moreover, the aortic knob tended to be unduly small and there were often dense lung roots without any congestive failure. These points distinguished stenosis from the goitre heart, which did not show such an extreme pulmonary arc or any conus bulge and in which the aortic knob was unaltered in size and the lung roots were only dense in the presence of heart failure.

The cause of goitre heart might be the greater volume carried by, and the greater pulsation of the great vessels; the weaker pulmonary arch would give way before the aorta.

The President asked for further details of the causation.

Dr. J. Parkinson said that these changes were found in a fair proportion of cases of hyperthyroidism and it was remarkable that the hearts of young people should be so affected. It had been stated that the lung fields were clearer in goitre than in the normal case, but others thought this was due to the emaciation. In mitral stenosis the lung areas would be more shadowed.

Dr. Cookson, in reply, said that measurements had shown that the pulmonary artery was actually dilated. Some German workers had suggested that the prominence of the pulmonary artery was entirely due to enlargement of the right ventricle. He did not think the lung fields were really any clearer than normal in goitre.

Dr. Adolf Schott (Bad Nauheim) read a paper on the

Respiratory Changes of Blood Pressure.

These changes, he said, consisted in a decrease in the amplitude of the pulse during inspiration and an increase in expiration. There were three forms of pulsus paradoxus: (1) the extrathoracic, which had no clinical importance; (2) the mechanical, due to adhesions between the heart and neighbouring structures; and (3) the dynamic, which was the subject of his paper. He described a number of experiments on animals and patients, particularly a method of direct registration, as a result of which he had found no connexion between pulsus paradoxus and latent or inherent weakness or atonia of the heart muscle. A pulsus paradoxus was found, however, over a wide range of pressures, in emphysema, even in very early cases where the diagnosis was only radiological. It was found also in artificial pneumothorax. These results could be explained by the fact that the intra-alveolar respiratory pressure changes were markedly increased and reacted on the pulmonary vessels. The practical conclusion was that pulsus paradoxus might indicate increased resistance in the bronchial and alveolar tubes, and could not be regarded as a sign of incipient atonia of heart muscle. A closer definition of pulsus paradoxus was advisable, and the dynamic form should be diagnosed only if the pulse tracing showed the characteristic respiratory changes when taken by an adequate recording system under no pressure outside the range: systolic pressure to 15 mm. below.

Dr. A. Brian Taylor read a paper on

Tuberculous Empyema.

This form of empyema, he said, differed from other forms and required different treatment. His paper was based on a series of 79 cases from the Brompton Hospital. A purulent tuberculous effusion indicated pleural tuberculosis, either primary or secondary; a clear effusion might be a secondary exudate or an allergic response. The morbid process in the pleura followed the usual changes of tuberculous lesions, but the frequency of early adhesions accounted for the comparative rarity of empyema. Only a few main ætiological types were common. In his series the onset had been as follows: (1) in an artificial pneumothorax, 47 per cent.; (2) by primary purulent pleurisy, 15 per cent.; (3) in a previous serous pleurisy, 16 per cent.; (4) after spontaneous pneumothorax, 22 per cent. The final diagnosis was made by finding the bacilli in the exudate, but often diagnosis had to rest on the presence of a sterile effusion, with a more or less chronic course and clinical features compatible with tuberculosis. The clinical course might, however, vary widely.

The treatment presented problems of the gravest difficulty and the prognosis was bad. Treatment must take into account: (1) the mechanical and toxic effect of the effusion; (2) the condition of the underlying lung; and (3) the general state of the patient. When the trouble in the lung was slight or controlled, where the pneumothorax was otherwise producing satisfactory results, or where the general condition was good, treatment should be energetic and radical. Removal of the effusion was best performed by gas replacement, which occasionally produced cure. More often, further treatment was needed, and pleural lavage was often very helpful. By continuing pleural lavage combined with gas replacement to keep the cavity dry and empty, the lung could be gradually re-expanded to such an extent that complete cure resulted. It was, of course, useless to re-expand a lung containing active disease, but expansion was fairly safe after two years. Pleuricotomy with constant drainage was a useful measure but seldom produced permanent cure. It was a temporary measure, or could be applied when the patient was too ill for radical treatment. Oleothorax had not proved very satisfactory at Brompton; it was mainly indicated in recurrent purulent pleurisies where the toxæmia was very severe, in cases secondarily infected before surgical treatment was commenced, or in the presence of pleuro-pulmonary perforations which might be healed by oil. Thoracoplasty was one of the most valuable methods; it brought the chest wall down to the lung to produce adhesions. It was the operation of choice when the active lung disease was unilateral, or where it had been locked up by fibrosis. Phrenic avulsion should be performed first.

Of the 79 cases in this series, 31·6 per cent. were alive three years after treatment, 58·2 per cent. dead within two years, and the rest untraced. Pleural wash-outs had been used alone in 18 cases, half of whom had died, and in addition to gas replacements in 57 cases, 52·6 per cent. of whom had died. Thoracoplasty in 13 cases had had a mortality of 30·8 per cent.

Dr. G. MARSHALL said that tuberculous empyema was almost always due to rupture of the lung, and treatment should depend on whether it was tuberculous or secondarily infected. If the purely tuberculous were left alone, most patients did well, but the secondarily infected had to be treated, preferably by continuous suction drainage, which was a tedious treatment but extraordinarily worth while.

Dr. E. R. CULLINAN read a paper on

Dermatomyositis.

This was, he said, a disease of unknown origin difficult to diagnose from scleroderma. It appeared to be an infection, but nothing else was known of its ætiology. He described a case which appeared quite different from scleroderma. The patient had complained of loss of power and a rash. She had had difficulty in walking and balancing, in feeding herself, and in clearing her throat. She had had vague generalised pains. The rash had been a patchy skin pigmentation; the skin had felt stiff and the subcutaneous tissue thick. All the joints had been stiff—some of the muscles had seemed to be in a state of tonic contraction, and had shown some reaction of degeneration. The chief reflexes had been absent. There had been moderate evening fever. She had gradually become worse, and had died in a manner suggesting suffocation from mucus which she could not dislodge. The peculiar changes in the muscles were apparently confined to dermatomyositis; they were never seen in scleroderma, however similar the two skin conditions might be. Autopsy had shown a marked lymphoid hyperplasia in the stomach, spleen, and thyroid, a general diffuse fine fibrosis, with wide areas of chronic inflammation (lymphocytes and histiocytes) in the muscles, and foaming macrophages in the areolar tissue. Some fibres showed a hyaline degeneration like Zenker's degeneration.

Dr. PARKES WEBER asked whether the urine had been examined for myoglobin, and what precisely was meant by lymphoid changes in the stomach and thyroid.

The PRESIDENT asked if the blood had shown any eosinophilia.

Dr. CULLINAN, in reply, said that the urine had not been specially examined for myoglobin; it had contained no albumin. By lymphoid hyperplasia he meant overgrowth of the lymphoid tissue in the subepithelial layer of the stomach, but there had been no definite appearance of follicles in the thyroid. There had been no eosinophilia.

SECTION OF UROLOGY.

AT a meeting of this section on April 21st, the chair was taken by Mr. RALPH THOMPSON, and a discussion on

Nephrostomy in Theory and Practice

was opened by Prof. HUGH CABOT of the Mayo Clinic. Nephrostomy, he said, was a very old operation as an emergency procedure, but the earliest discussions on the subject did not appear to date back beyond the 'eighties. The rapid return of function and the effect, upon infection, of drainage through the kidney substance had attracted attention at that time. He would, he said, consider the application of nephrostomy in three types of case—namely, calculus disease; chronic hydronephrosis with or without infection; and chronic infection of the kidney. Nephrostomy was desirable in calculus disease when the pelvis and calyces of the kidney were markedly dilated, and he believed that the operation diminished the risk of infection considerably in the non-infected cases; there was, however, [illegible] the operation might stir up latent [illegible] the kidney had been primarily injured by stone, and had subsequently been the site of prolonged infection, it was a temptation to regard nephrectomy as the only safe operation; but if there were stones, however small, on the opposite side he hesitated to recommend nephrectomy. Moreover, in a number of instances where the stone-bearing kidney on one side had been removed, stone had developed in the opposite kidney although it might have been healthy for years. In one sense a stone-bearing kidney on one side might be a safeguard to the other kidney. Possibly on the removal of the stone-bearing kidney the disturbance of chemical mechanism, whatever it might be, was transferred to the previously healthy kidney. For these reasons he was unwilling to perform nephrectomy where it could be avoided, and preferred to do as much as possible for the injured kidney, however serious the damage might appear to be. Cases of pyonephrosis without stone also fell into this group, and were undoubtedly the outcome of infection of a hydronephrosis. It had been recognised for many years that, although it was not possible to determine with any accuracy how much the function of a kidney containing a stone was depressed, removal of the stone would often result in a return to something approximating to normal function. In cases of pyonephrosis, however, the kidney was often reported to be completely functionless. This did not necessarily mean that the kidney was incapable of function. In a series of 42 cases in which no function other than moderate secretion of water could be detected, he had found that drainage of the kidney and removal of stone, where stone was present, resulted in a return of about 50 per cent. of the normal function. It was, therefore, unjustifiable to declare a kidney incapable of function, even when it failed to respond to the elaborate tests now available. In the normal kidney only a certain proportion of the glomeruli were active at any one time, and under adverse conditions it might be possible for the whole kidney to lie fallow for a considerable period. If the active glomeruli were reduced from about 30 per cent. to about 3 per cent. the kidney might possibly continue to preserve its anatomical structure and capacity for normal function. Nephrostomy was valuable as a method of estimating the capacity of a kidney which appeared to be functionless. An advantage of nephrostomy over pyelostomy was the provision of more satisfactory drainage. His experience had been that kidney function would return after drainage in proportion to the amount of normal kidney tissue remaining. Opinions differed on the effect of nephrostomy in clearing up infection. Acute recent infections generally cleared up entirely, but were relatively rare among the cases in which the operation was indicated. Recent and slight infection of an acute hydronephrosis usually cleared up readily whatever method of drainage was employed, provided the obstruction was removed. With chronic infection the question presented difficulties; at the Mayo Clinic there were a number of patients who had been draining for some years following nephrostomy, and who were retaining a kidney of some value. A kidney which had been severely infected at the outset usually continued to harbour urea-splitting organisms, but it might serve as a useful organ, nonetheless, which was worth preserving if the opposite kidney was injured. Where both kidneys were damaged it was worth while trying to preserve a kidney of this kind; he did not think there was evidence to support the view that such a kidney menaced the kidney of the opposite side. He believed that nephrostomy had a wider field of application than was usually conceded. In cases of doubt the function of an infected kidney might be saved by the operation, whether stone was present or not. In certain cases, particularly cases of cancer, permanent nephrostomy might be valuable, and was not more socially inconvenient than permanent colostomy: the patient might live comfortably for many years. The tube could be so arranged as to be accessible to the patient, who could change it himself after a little experience. He shared the view, put forward in 1910 by Watson, that in bilateral calculus disease, permanent nephrostomy on one or both sides might preserve the kidney tissue from further destruction. It was even possible that in some cases permanent nephrostomy might inhibit the development of further calculi in the kidney, though the evidence on this point was inconclusive. At his clinic there were patients operated on for recurrent calculi who had lived for 3, 6, and 15 years after permanent nephrostomy without further recurrence. Two other cases had been reported in which permanent nephrostomy had been performed for recurrent calculi, and there had been no further recurrence. In Watson's case in 1910 not all the calculi had been removed, but there was no evidence that they increased in number following permanent nephrostomy, and the patient lived for 25 years with good kidney function.

Sir JOHN THOMSON-WALKER remarked that in this country the term nephrostomy was used to imply an operation leaving a permanent fistula, and nephrotomy was reserved for temporary drainage of the kidney. Conservative treatment was favoured in cases of bilateral calculus, but it had not been his experience that removal of stone from one kidney favoured the development of stone in the other. On the contrary, it had been found that if an infected stone was left in one kidney, there was a tendency for stone to develop in the opposite kidney.

Mr. JOCELYN SWAN doubted whether the apparent improvement in renal function following drainage was a true improvement. The stone might depress the action of the kidney in the earlier tests, and the apparent restoration of function following removal of the stone was therefore deceptive.

Mr. F. A. G. JEANS and Mr. ZACHARY COPE also joined in the discussion.

Prof. CABOT, in replying, said that nephrostomy was not an operation which should be substituted for nephrectomy if the other kidney was sound.

THE MEDICO-LEGAL SOCIETY.

AT a meeting of this society on April 28th, with Lord RIDDELL, the President, in the chair, a paper on the

Gynæcologist in the Law Courts

was read by Mr. J. BRIGHT BANISTER. He said he believed that most gynæcologists felt an abhorrence about appearing in the law courts, first because the cases concerning which they were required to give evidence were usually sordid and unsavoury, and secondly because a gynæcologist in active practice found his work seriously dislocated by the inevitable delays associated with legal hearings. Further reasons were that the evidence he had to give was hard to present to the non-medical mind, which usually was very ignorant of the subject. Recently, for example, a successful barrister was much annoyed with a doctor because X rays had not been employed to settle the mystery of a possible six weeks' pregnancy. The gynæcologist's difficulties were not lessened by the fact that usually he knew nothing of the law; it took him a long time to realise that law and equity were not related to one another. Even the oath appalled him, for it required the telling of "the truth, the whole truth, and nothing but the truth." A medical examination was made, and certain facts were noted, which, communicated to the court, were, to the doctor, the truth; but if other facts not noticed were not included it was not the whole truth. And in the interpretations and inferences drawn, the witness was made to feel that his completed evidence was something more—it might even be less—than the truth. Even the words he used were sometimes altered, as in a case in which he referred to a woman's abdomen, and the judge interposed with the remark to the jury: "When the doctor says her abdomen he means her stomach."

Mr. Banister's main purpose, he said, was to relate some of the reactions of a gynæcologist to his experience in the courts. He thought a distinction should be drawn between the gynæcologist and the ordinary medical witness and that the former should be regarded as an expert, for he was required to maintain an impartial outlook on all the circumstances at issue. The examination-in-chief and the cross-examination were apt to produce on the witness one of two effects: either he became antagonistic and so lost his impartiality, or he realised that anything was possible in gynæcology, as in other branches of the profession, and so was of little use to any one side, especially as he heard evidence by other medical witnesses which was at variance with his own. Mr. Banister therefore thought that a medical witness on a subject should be one who had experience of it in actual practice. In one case a medical witness, who said he had been 30 years in practice and had commanded a general hospital during the war, gave evidence to the effect that a cystocele was a cyst containing fluid, and so could not be in the genital canal of a woman—though he had never seen a cystocele. Another medical witness in the same case admitted he did not know what a cystocele was. What was the position of the medical witness who was to follow ?

Another thing to remember was the attitude of the law towards the class of case in general in which the gynæcologist was called as a witness : lawyers in the case were sure to give weight to the published abnormalities associated with the generative function. On a question of the division of an estate on the presumption that a woman advanced in years would not bear any more children, the experience and knowledge of the gynæcological witness was largely nullified by counsel quoting cases—some not well authenticated—of women having given birth to children at an advanced age. Early last century it was stated that a woman, aged 69, had given birth to a child, but it was now agreed that there could be no childbirth after the age of 52. Again, the law presumed that pregnancy could not occur until some degree of menstruation had been set up, but some years ago a girl, aged 10¾ years, was brought to hospital and was delivered of a normal child weighing 8 lb., though no one connected with her knew of her having had periods at any time. The important matter was to get all possible evidence in regard to the particular patient.

One of the most difficult things was to stand up in the witness-box and say that a particular patient was *not virgo intacta ; it would be easier to say she was so.* Cases had been reported in which a baby was born to a mother who, to all appearances, had an intact hymen. Another difficulty was to say, in an old-standing case, whether a woman had had venereal disease, and in this connexion Mr. Banister criticised the carefully guarded attitude of some pathologists who declared themselves uncertain those presented with a slide of discharge from the patient in question.

Mr. Banister thought medical cases would be more satisfactorily settled if a medical assessor could sit to advise the judge on technical points.

DISCUSSION.

Sir BERNARD SPILSBURY thought that the gynæcologist was usually regarded by the courts as an expert, not on the same level as a general practitioner. He agreed that a real difficulty, when cases were heard in court, was having unusual or very rare cases quoted against a considered opinion. And many of the cases in the literature were not well authenticated, and under present conditions would not be accepted as reliable. As regards the diagnosis of virgo intacta he mentioned a case in which destruction of a child's hymen was due to threadworms, and until the cause was known suspicion of foul play was entertained. He did not think any pathologist should hesitate to give a firm opinion on the discharge in an early case of gonorrhœa. In a later stage, however, the genital tract swarmed with bacteria, and the gonococci were so far diluted that sometimes it was not safe to express a positive opinion.

Mr. F. J. MCCANN pointed out that the medical man could state whether a hymen was present or not, and also describe the condition in which it was found, but it was quite another matter to say that a girl was virgo intacta. He had never yet seen a girl with a hymen congenitally absent, though witnesses in court had often made a strong point of the possibility of its congenital absence. Many cases of vulvitis were treated on the assumption that they were gonococcal when they were not, and the reprehensible habit of syringing—which served to carry the infection still higher—was responsible for destroying many hymens. The acute stage of gonorrhœa was easy to recognise, but in women the diagnosis in a chronic stage was difficult. An important point was, that if one could discover, with the urethral infection, involvement and enlargement of the glands of Bartolini, one could be certain that the condition was gonorrhœa.

Sir WILLIAM WILLCOX objected to the appointment of assessors to help the judges ; he believed that in general the best assessor was the British jury. The present system worked well. When, owing to lack of means, no expert was giving evidence on the other side, he made it his practice to give a general review of the case from the medical aspect.

Mr. W. G. EARENGEY, referring to the telling of the whole truth, said that if doctors were going to set out to tell the court all they knew about the subject at issue, there was likely to be a long extension of hearings. And doctors should not have the idea that they were ranged on to a side in the case ; they were called to supply important information.

Dr. J. WATKIN EDWARDS approved of the appointment of an assessor to assist the judge ; one did not want in that post a man who could analyse evidence, but one well acquainted with the subject under consideration.

The PRESIDENT expressed his objection to the appointment of assessors. If such were appointed they would not be very popular among their professional brethren, who did not think very much of each other personally, though they were ready to coöperate against the rest of mankind! Their critical attitude was of much service in the courts. In order to obviate the great waste of professional time the courts required a business manager, who would so arrange cases that there was little waiting on the part of witnesses and counsel. He was firmly convinced that the British system of administration of justice stood in need of no emendation. As to the age beyond which it was not possible for a woman to conceive, he once offered a prize of £40 for the discovery of the oldest mother, and the winner was a woman aged 53 years 224 days ; mother, father, child, and doctor attested to the fact.

Mr. BANISTER replied that he did not feel there was any want of considerate treatment by the courts of the gynæcological witness ; his chief complaint was about the great amount of time such witnesses, with others, were obliged to waste.

ORTHOPÆDIC HOSPITALS.—*At the annual meetings* of the Shropshire Orthopædic Hospital, Agnes Hunt Surgical Home, and Derwen Cripples' Training College it was stated that 1540 in-patients, 707 of whom were children, were treated last year. The average stay of each adult was 110 and of each child 73 days; there were 598 operations. There are 33 after-care centres which in 1931 treated 4403 patients. New buildings for the training college to accommodate 100 students are nearing completion. They have been built by direct labour, much of it by the cripples themselves. On account of the very severely crippled type of student admitted to the college, the Board of Education has sanctioned an increase in the fees from 25s. to 35s. per week.—Two patients, one in the uniform of a Scout and the other in that of a Guide, recently laid the corner-stone of the new Princess Margaret Rose Ward of the Bath and Wessex Children's Orthopædic Hospital. The cost of the ward, £6500, is being defrayed by Mr. Stanley Wills.

REVIEWS AND NOTICES OF BOOKS

A Text-book of Psychiatry.

Third edition. By D. K. HENDERSON, M.D., and R. D. GILLESPIE, M.D. London: Oxford University Press, Humphrey Milford. 1932. Pp. 595. 18s.

Essentials of Psychiatry.

Second edition. By GEORGE W. HENRY, A.B., M.D., Assistant Professor of Psychiatry, Cornell Medical School. New York. London: Baillière, Tindall, and Cox. 1931. Pp. 304. 21s.

THE valuable text-book by Drs. Henderson and Gillespie is now the fullest and most satisfactory single exposition of Anglo-American psychiatry available. Though it is less comprehensive and detailed than the comparable Swiss and German text-books, and oddly capricious in the selection of recent work for notice, its authors have evidently taken trouble to make the work a reasonably complete manual. An informative, cautious chapter on the psychiatry of childhood has been added, and the chapters on epilepsy and legal aspects have been expanded. The section on paranoia and paranoid reaction-types is unsatisfactory, and a notable omission is the failure to refer to the recent work of Kolle in this field. The psychopathology still gives the impression of a patch, perfunctorily inserted, rather than matter incorporated into the pattern of the work as a whole. The value of the book would be enhanced if all references were given in full, instead of merely the name of the writer under discussion. It is hard to see the justification at this date for a separate chapter on psychoses and psychoneuroses in war. It would be a pity if so useful and handy a work were to become unwieldy through increase, and consequently suffer a falling off in its popularity among medical students and others; but if it could be done without making the book too bulky, a fuller discussion of psychopathic personality and of the general principles of treatment would be an advantage in the next edition.

There will inevitably be differences of opinion as to which are the essentials of psychiatry. Dr. Henry's book presents in direct and unpretentious form that broad, rather than precise, approach to the subject which has come to be characteristic of the American school. An emphasis on total reactions, on environmental influences, on personality and habit-formation, may be regarded as giving the best background and introduction to the study of this most intricate branch of medicine, especially if therapy be the end in view, rather than research. But one would expect more than a line or two to be given to the hereditary aspects of mental disorder, or, in another field, to the malarial treatment of general paralysis of the insane. General principles, however, and the psychological and social approach have been the author's chief concern, and the book is well-balanced from this point of view. Less than half of it is occupied with descriptions of abnormal syndromes; the major part consisting of chapters on methods and purpose of examination, principles of treatment, mental hygiene, psychopathology of the normal, medico-legal and historical aspects, and psychiatry in the general hospital. There are also excellent chapters on psychiatric nursing (by Adèle Poston, formerly matron at Bloomingdale Hospital), and on psychiatric social service. The work has been considerably rewritten and enlarged for this second edition.

Fertility and Sterility in Marriage.

By TH. VAN DE VELDE, M.D., formerly Director of the Gynæcological Clinic at Haarlem. London: William Heinemann, Ltd. 1931. Pp. 448. 25s.

THIS is the third of a trilogy of books written by Dr. Van de Velde of which the first, "Ideal Marriage," was reviewed in 1929.[1] The author has here set himself the difficult task of writing both for the medical and the lay public and, as is to be expected, the work suffers from this dual intention. The medical reader will find in it much tedious description of the anatomy and physiology of the reproductive organs; the lay reader will encounter throughout the book disconcerting outcrops of technical terms the meaning of which he will not understand. But the book suffers from another defect which will distress both classes of readers. The author does not confine himself to describing and interpreting the relevant facts. He generalises freely on moral and religious questions. Thus he is at pains to differentiate the ethical position in regard to contraception which he personally adopts, from that assumed by moralists and ecclesiastics; he condemns, on a priori moral grounds, the legalising of abortion without any reference to the vexed question whether the measure would diminish maternal morbidity and mortality; he introduces into the text of his book two "intermezzos of aphorisms" which do not add to its scientific value; and he expresses himself as follows on the subject of religion: "In my opinion, religion is of enormous importance, for individual happiness; I consider religious belief and 'illusion,' 'fiction,' and 'vital hypothesis' of the first rank, offering many human beings such help and support in the conduct of their lives, that, to them, life would be insupportable without such belief." The illusory, fictitious, and hypothetical characteristics of religion are then dealt with at length. It may be felt by medical readers that the tone of the book suffers from the fact that the author dogmatises too freely in the first person on moral questions.

However that may be, Dr. Van de Velde deals informatively with a wide range of subjects. The attitude taken by the Roman Catholic Church, the population question, the problems of differential fertility, and the personal implications of contraception are instructively discussed in the first part of the book which is devoted to "ethical postulates and principles." In the second part, chapters on the physiology of reproduction and the prevention of pregnancy precede an exhaustive discussion of the causation, treatment, and prevention of sterility in women, and of impotence in men. There follow chapters on artificial fertilisation and contraception. In the latter appears a condensed and, from the standpoint of this book, irrelevant account of the various positions in which coitus may take place. Dr. Van de Velde has already given an elaborate presentation of this theme in "Ideal Marriage" which has been copied by other writers and is one of the fullest in the English language. The book contains further chapters on sterilisation by surgical, biochemical, and radiological methods. The author has invented a somewhat elaborate operation by which he claims temporarily to sterilise female patients. It consists of an incapsulation of the ovaries in the uterovesical pouch. The ovaries are thrust forward through an incision in the broad ligaments, after which the uterus is sewn over them to the bladder. In order to unsterilise the patient, the operative procedure is reversed. The operation is not, in our view, likely to be favourably received, for it is open to many criticisms.

---

[1] THE LANCET, 1929, ii., 177.

Twenty plates illustrate pelvic anatomy, ovarian segmentation and implantation, operative procedures, and contraceptive appliances. The author's tendency to dogmatise is evident in his treatment of scientific no less than of ethical subjects. He leaves few topics sub judice and he makes at least one assertion which has been disproved—namely, that the intra-uterine silver ring *must* have an injurious effect upon the child if a pregnancy occurring despite the presence of the ring goes to term. On the last page of the book is given the address of a manufacturing chemist from whom a contraceptive jelly invented by the author may be purchased. There are 317 references to other books and papers, mostly in German, which are not arranged in alphabetical order. Many of these have but a distant bearing on the subject, while some important recent work in this country is not noticed. There is no index. The translation is competent and the book, as a whole, is readable.

1. Exercise and its Physiology.

By ADRIAN GORDON GOULD, Ph.B., M.D., Assistant Medical Adviser and Assistant Professor of Hygiene in Cornell University; and JOSEPH A. DYE, A.B., Ph.D., Assistant Professor of Physiology in Cornell University. New York: A. S. Barnes and Company. 1932. Pp. 434. $3.

2. Physiology of Exercise.

By FERDINAND AUGUST SCHMIDT, M.D., late Director of Health of Bonn, Germany; and WOLFGANG KOHLRAUSCH, M.D. Berlin. Authorised translation by CARL B. SPUTH, M.D., Dean of the Department of Science and Hygiene, Normal College, A.G.V., Indianopolis Ind. Philadelphia: F. A. Davis Co. 1931. Pp. 216. $2.50.

1. Though no original matter is included in this work, it provides one of the most complete expositions of the subject that has appeared. It is clear that the available literature has been surveyed, and that a careful selection of essentials has been made. The result is encyclopædic, and forms an invaluable work of reference to be studied rather than read. Although the authors express their intention of avoiding technical terms, the book is not easy to read, a condition which arises not from ambiguity nor confusion of expression, but from their determination to be comprehensive and exhaustive. Few students, even of advanced physiology, would readily find themselves able to define the relation between phosphocreatine and the formation of hexosemonophosphate, or the connexion between a rheobase and chronaxie, or the five conclusions which can be drawn from a study of the stimulation of single muscle-fibres. These are examples picked at random among the questions submitted at the termination of the chapters in the early part of the book, and are advanced only to show that complete understanding of the work will demand careful study. The arrangement of the chapters is excellent, and an admirable summary is given at the end of each.

2. It is claimed in the preface that this translation of the late Dr. Schmidt's "Physiologie der Leibesuebungen" is one of the most complete works on the physiology of exercise. Such a claim can hardly be accepted; since, although the general physiological principles relating to exercise are included, they are considered in too superficial a fashion to compare with the elaborate treatises on the subject which a serious student would require. Nevertheless, this book can be warmly recommended as something quite different from the usual presentations, for it is the dynamic and mechanical aspects that are particularly emphasised. It should make an appeal to the student of athletics who is satisfied to skim lightly over the scientific principles, and who is not in a position to assimilate the details of advanced physiology. Considerable emphasis is laid upon the differentiation of constitutional types, and an attempt is made to correlate anatomical characteristics with physiological attainments. Such criteria are supported by reference to famous contemporary athletes, and the arguments are sustained by attractive action photographs and cinematograph studies. In this respect the author is sometimes rather too enthusiastic, as when he aspires to advise a young man upon the kind of sport in which he may expect to excel. "We must be able," he says, "to base our judgment on the expression of his face and on his character and temperament as well as on his physical fitness." But on the whole sound common sense accompanies accurate information. We are thoroughly in accord with the wisdom of the warning that, though much interest attaches to the investigation of the mechanics of the joints and muscles involved in complex activities, little is to be gained by an attempt by minute analysis to explain the forces which make for successful performance of a difficult feat.

The translation has been admirably conducted. The language is vivid, and only occasionally do such expressions as "booster," "lose out," "all in" contribute a transatlantic flavour. Evidence of a critical eye is afforded by occasional corrections of the original text.

REPORTS AND ANALYSES

MARTELL'S BRANDY.

(J. AND F. MARTELL, COGNAC.)

WHEN submitted to analysis this brandy, the well-known "Martell's Three Star," gave the following result:—

Alcohol by volume per cent.	39·54
Proof spirit " "	69·20
Alcohol under proof "	30·8°
Extractives containing sugar per cent.	0·62
Total acidity as acetic acid per cent. ..	0·032
Apparent specific gravity	0·9546°

Secondary products expressed as parts per 100,000 of absolute alcohol:—

Acidity (acetic acid)	33
Aldehydes	25·3
Furfural	5
Esters as ethyl acetate	88
Higher alcohols	135

The analysis of the secondary products shows without doubt that this brandy is genuine, but it is not possible to judge the quality of a brandy from figures alone. Palate and other physical characteristics are still the pre-eminent criteria. The evidence of taste here goes to prove that the sample submitted was an old-matured cognac grape spirit.

We last analysed this well-known brandy some twenty-seven years ago and are glad to be able to state that the evidence both of analysis and taste indicates that the high standard of purity and quality has been maintained, and that the brandy is eminently suitable for medicinal purposes.

"CHARKAOLIN"

GRANULES

"Charkaolin" is a highly efficient agent for the treatment of intestinal infections characterized by abnormal fermentation and the formation of toxins. It combines the absorbent properties of highly activated vegetable charcoal with the well-known toxin-adsorbing qualities of "Osmo" Kaolin.

It is in the form of fine, clean granules which disintegrate rapidly in water and diffuse their ingredients evenly throughout the liquid. "Charkaolin" is tasteless, forms a fine suspension in water and is, therefore, quite easy to take.

In bottles at 2/6 each.

TABLETS

The "Allenburys" "Charkaolin" Tablets provide a convenient alternative method of administering "Charkaolin." Particularly suitable when travelling. Tasteless and disintegrate readily.

In bottles:
40 tablets - 1/6
80 tablets - 2/6

THE LANCET.

LONDON: SATURDAY, MAY 7, 1932.

HOSPITAL THRIFT.

Lord Lloyd has lent his name and fame to a scheme for meeting the needs of those who now find it difficult to get treatment of serious illness at a price within their means. The attractive features of the British Provident Association for Hospital and Additional Services are that its benefits are fully enjoyed by the subscribers to it—the whole of the funds, after payment of administrative expenses, will go to the provision of benefits; and the benefits themselves are guaranteed and underwritten. The only charitable element in the scheme is the advice and experience of its executive council, which is given free of charge, and a loan by the Pilgrim Trust of funds sufficient to make a start. The benefits offered are in brief these. For an annual subscription of a guinea in the case of a single man or woman; a guinea and a half for married couples; or two guineas for a married couple with one or more dependents, a sum of £5 a week for a period not exceeding three weeks will be available if the subscriber or dependent has been admitted for any reason to a hospital, or to a nursing home for a necessary surgical operation. An addition of 50 per cent. to the subscription will extend this benefit to a period of six weeks. If a subscriber or dependent is attended at home on account of an operation or dangerous illness by a resident nurse, a sum of £3 3*s*. per week is available for not exceeding three weeks. For a consultation, when the medical attendant is in doubt or difficulty, a sum of £1 1*s*. is available towards the fee of a consultant at his rooms, or £3 3*s*. if he visits a patient who cannot leave home. For treatment at the Radium Institute (with which no doubt it is intended to associate the Mount Vernon Hospital) one-half of the charges up to a maximum contribution of £40 is available in any year. A subscriber is entitled to the use of an ambulance up to the value of £1. Finally, a limited proportion of funds is put by to maintain subscribers and dependents in a nursing home in cases of dangerous illness other than a surgical operation. This is the basic subscription and benefit. A graded addition to the subscription entitles a subscriber or dependent to contributions towards surgeons' fees up to a maximum of £25, £50, and £100 respectively. And finally another increment of twelve shillings and sixpence in the case of a single man or woman will provide £1 1*s*. a day up to 20 days towards the fee of a consulting physician in attendance during treatment in a hospital or nursing home. These are the benefits offered, and it is to be understood that they do not include any help towards the fees of a general practitioner, assistance in the case of maternity, tuberculosis, infectious or mental disease, or the services of an ophthalmic surgeon except in respect of some specific disease. While there is no age limit to membership it is obvious that persons suffering from chronic illness cannot be accepted, and except in cases of emergency the benefits are available only upon the recommendation of the medical practitioner in attendance. A subscriber's child is regarded as dependent only up to the age of 16 years. So far the scheme will indemnify the subscriber against the cost of stay in hospital or nursing home, but it does not completely solve his problem unless he can find a private bed available at an economic weekly charge. The Association has come to the conclusion that he cannot rely upon this, and, in addition to the mutual and coöperative scheme, it has evolved a founders' scheme by which an individual, for a single payment of £10, can secure for himself and his family the first call upon a private bed for which he will pay only the actual cost of maintenance. Experience and inquiry has satisfied the directors that a properly equipped private bed costs on the average no more than £1000, and suffices for the sickness of a little more than 100 families. The beds contemplated in this scheme have yet to be built, but in the meantime arrangements have been made with a number of hospitals under which private beds will be immediately available, and more permanent arrangements are in contemplation.

The history of the movement is not devoid of interest. In 1921 the late Dr. Gordon Dill, of Brighton, started a scheme in Sussex to provide hospital maintenance and treatment on the basis of a yearly voluntary subscription of a pound per annum for an individual, thirty shillings for a married couple, two pounds for married persons with children under 16 years of age, the income limit being £250, £400, and £500 respectively. The facilities were available only on the application of the patient's family doctor and with the approval of the members of the hospital staff concerned. Beside hospital treatment the subscription was planned to cover consultation where necessary at home, dental treatment, laboratory investigations, nursing services, and the use of an ambulance. After some initial criticism this scheme gained the approval of the medical profession in Sussex, and began to attract attention elsewhere. Nine of the general and special hospitals in Sussex agreed to cooperate, and the result has proved of equal value to the hospitals concerned as to the subscribing public. Having set his scheme going in Sussex, Dr. Gordon Dill widened his sphere of influence, and with the cooperation of Sir Arthur Stanley, Sir Alan Anderson, Lord Dawson, Mr. McAdam Eccles, and the late Viscount Knutsford, initiated the National Provident scheme for hospital and additional services, giving of his time and energies without stint. In 1923 this national scheme was incorporated in the British Provident Association, and began a decade devoted to collecting and tabulating facts and figures on which to base a comprehensive scheme on a larger scale, Mr. Eccles taking Dr. Dill's place as instigator. In

1927, when King Edward's Hospital Fund for London set up a committee of inquiry, the Association put before it the results of their investigations, with the result that the committee recommended the organisation of an effective scheme of mutual provision for middle-class patients against the cost of treatment and the exploration of a scheme of subscription to the capital cost of the new pay beds which would be needed.

This larger comprehensive scheme has now been launched with the double stimulus of a successful object-lesson and of a period of economic pressure in which the haphazard arrangements of a more bountiful time are unlikely to survive. The Sussex Provident scheme has been a remarkable success; at the end of last year its subscribers numbered 30,374, covering themselves and more than as many dependents. Last year distribution was made in respect of treatment for members to an amount of nearly £15,500 to the coöperating hospitals, representing £2 4*s.* 11*d.* a week for every in-patient in the Brighton area. Coöperation has been secured with practically every hospital in the area, Worthing Hospital having come in during the past year, and arrangements have been made with public assistance committees where treatment is given at transferred hospitals. At the recent annual meeting Sir ARTHUR JENNINGS, in moving a vote of thanks to the chairman, said that nothing was better evidence of the value of the system than the fact that everyone was now trying to imitate it; and Sir PHILIP CRAWLEY, in response, said he thought as time went on hospitals would have to rely more and more on these contributory schemes for their assured income. Voluntary hospitals do not stand to gain so much directly from the British Provident scheme because it has surrendered to the Hospital Saving Association the class of patient entitled by a means test to occupy hospital beds; and this Association contributed last year half a million pounds to voluntary hospitals in London. Indirectly, however, the scheme will benefit these hospitals enormously by preventing their abuse. Outside London, voluntary hospitals are coming to depend more and more upon contributory schemes of various kinds. If the British Provident Association makes good as the Hospital Savings Association has done, they should together help the London voluntary hospitals in the way best suited to their needs.

◆

UNDULANT FEVER.

THERE are probably few diseases in this country at the present day which present so many features of interest as the condition rightly or wrongly termed undulant fever. To the epidemiologist its incidence and the method of infection are fascinating problems; to the bacteriologist its diagnosis and the differentiation of the various types of invading organisms afford ample scope for inquiry and ingenuity; to the clinician it is a stumbling block of the first order; to the hygienist its prevention calls for a profound study of the main channels of infection; and to the veterinarian, though undulant fever in man is of but secondary interest, contagious abortion of cattle, which is the chief source of infection both in animals and in human beings, is a disease whose control and ultimate eradication are attended by as many difficulties as those of tuberculosis itself.

Our knowledge of the extent of undulant fever in Great Britain is strangely deficient, and there are many who are prepared to minimise its incidence. We do know, however, that during the past five years a number of definite infections with an organism of the brucella group have been recorded; that in the few instances in which complete bacteriological typing has been performed the organism has proved to be of the bovine *abortus* variety; that whenever a number of blood-sera from patients with undiagnosed pyrexia are examined, a smaller or larger percentage are found to contain agglutinins to brucella in a titre probably indicative of active infection; that contagious abortion in cattle is an extremely widespread disease; and that a fairly high proportion of raw market milk contains living *abortus* bacilli. We know that infection with *Br. abortus* frequently gives rise to no clinical symptoms of disease, in this respect resembling infection with the tubercle bacillus. We know, too, that when active disease does occur it is of so protean a nature that a diagnosis is possible only by bacteriological investigation. A few cases, it is true, exhibit the typical pyrexial curve that suggested the name undulant fever, or one of the variants described by Sir W. DALRYMPLE-CHAMPNEYS in our issue of April 9th (p. 791); in most, however, the clinical symptoms are so little characteristic that the disease is diagnosed as influenza, tuberculosis, enteric fever, appendicitis, rheumatism, broncho-pneumonia, or some other condition. With these facts before us it is clear that we can have very little idea at the moment of the real incidence of *abortus* infections. In Denmark, where the Central Serum Laboratory at Copenhagen examines bloods collected from the whole country, and where during the four years 1927–1930 inclusive over 18,000 specimens of sera were examined from patients with undiagnosed pyrexia, cases of undulant fever have been recognised at the rate of four or five hundred a year. In this country it is by no means a routine practice to test Widal bloods against brucella, and probably only a few hundred sera have actually been examined for agglutinins to this organism. If the practice became general of sending in sera for examination from all patients with pyrexia whose cause presented the slightest doubt, and if all sera were tested against *Br. abortus*, it might well be found, as it has been found in Denmark, that undulant fever is commoner than typhoid and paratyphoid fever put together.

Bacteriologists are paying increasing attention to the prevalence of this disease, and it is gratifying to note the excellent studies on this subject which have recently been conducted in Scotland. One of these, by Dr. C. P. BEATTIE, of Edinburgh, is published in our present issue, and another, by Dr. J. SMITH, of Aberdeen, appears in the April number of the *Quarterly Journal of Medicine.*

BEATTIE has examined 28 blood-sera sent in from the city of Edinburgh for Widal examination, and found that five, of which at least four came from patients with undulant fever, agglutinated *Br. abortus* to a titre of over 1/100. He has also examined 47 sera from the surrounding counties, and obtained two significant reactions amongst them. SMITH, in an examination of 373 Widal sera from Aberdeen and the surrounding country, has encountered 11 sera reacting at 1/100 or over to *Br. abortus*, ten of which came from patients with clinical symptoms compatible with those of undulant fever. If we include the figures published by R. CRUICKSHANK and W. J. BARBOUR [1] in the Glasgow area, we find that of a total of 498 Widal sera examined in Scotland no fewer than 16 positive reactions were obtained in patients subsequently shown to be suffering from undulant fever, a proportion of 3·2 per cent. This figure may be compared with that of 3·1 per cent. obtained by M. KRISTENSEN [2] in Copenhagen as the result of examining 17,778 Widal sera. The mode of infection of the patients in Scotland is not altogether certain, though both BEATTIE and SMITH are inclined to the view that milk is mainly responsible. Examining the ordinary retailed raw milk in Edinburgh, BEATTIE found that 29 out of 83 samples, or 34·9 per cent., contained living *abortus* bacilli, while SMITH, in Aberdeen, states that 28·6 per cent. of samples of milk received directly from individual dairy farms was found to be similarly infected. Careful inquiry in the Aberdeen series of cases revealed the fact that a number of the patients had consumed raw milk, and that five of the patients had consumed raw milk which was definitely shown to be infected. Except in one case, direct contact with infected animals seems to have been excluded. It is noteworthy, however, that both in the Scottish and in the English series of cases undulant fever has been observed in town patients consuming very little raw milk, and that only in tea or coffee. How infection occurs in these cases is most puzzling. It seems fairly certain that most people who drink infected milk do not develop active infection, and it must therefore be postulated that some peculiar factors are necessary before the disease can develop in its typical form. What these factors are is a problem urgently awaiting investigation. It is possible that some other vehicle of infection, which has so far escaped notice, may be responsible for some cases. In this connexion it may be remembered that both the Dutch and the American workers have drawn attention to the frequency of *abortus* infections in horses and in dogs. It is as yet too early to say whether these animals are concerned in outbreaks of human disease, but this possibility must be borne in mind. In the United States, particularly in the middle west, hogs are very frequently responsible for human infection, but in Great Britain, so far as we are aware, no case of *abortus* infection in pigs has yet been recorded. Our ignorance of the epidemiology of undulant fever calls for intensive inquiry by all types of workers. Investigations of the nature of those carried out by Dr. BEATTIE and Dr. SMITH will be welcomed by all who are anxious to obtain sound knowledge of this puzzling disease.

◆

NOISE.

THE supposed influence of noise in causing an increase of nervous illness has often led to demands that the subject should be officially investigated, but as soon as investigation is seriously considered what seems to be a simple problem takes on an extraordinary complexity. That noise in our cities has increased is a ready assumption contradicted by the fact that 100 years ago the congregation of a City church complained that the noise of stage coaches drowned the voice of the preacher, and medical writers of the eighteenth century were emphatic about the alarming increase of nervous disorders. Noise is a nuisance, and to be compelled to raise one's voice or strain one's attention because of extraneous sounds may be worse than annoying. We have definite knowledge about auditory fatigue, such as is experienced after an aeroplane journey, and about that auditory degeneration which follows long exposure to noise and appears as an occupational disease like boilermakers' deafness; and from this positive knowledge it is easy to go on to picture the everyday noises of civilisation producing some physical effect upon nerve structures and thus causing those disorders loosely called nervous.

Some picture of that sort is probably present in the minds of many people who declaim about the curse of noise, but it need only be mentioned to be dismissed. The noises that cause irritation and exasperation possess no physical qualities that can be statistically correlated with those emotional states; indeed, as soon as the matter is approached with the aim of securing material to which statistical methods can be applied a mass of contradictions is at once manifest. To attempt a physical definition of such noises is impossible; what may be a joyous sound to the youthful rider of a motorcycle may be torment to the light sleeper in a quiet village, and that which is music on one side of a wall may become almost a physical assault when it penetrates to the other. There are some sounds that nearly everyone will agree to call unpleasant, and many other sounds that are unpleasant only to some people; so that when complaint is made of a noise the only certainty about it is that the person complaining does not like it. Moreover, experience of individual complaints provides an extraordinary range of aversions. At one end are sounds—that of the pneumatic drill in our London streets, for example—about which there is general agreement; then come sounds—such as thunder—highly disturbing to some people and mildly interesting to others; then at the extreme are stimuli, neutral to most of us, which produce in some individuals reactions of such intensity as to be equivalent to phobic states. Fear of thunder may be of this nature, and was notable as a psychoneurotic symptom in post-war cases. Strongly marked aversions may be so specific to the individual that a personal significance must be assumed, and cases have been recorded in which that significance has been revealed by methods of mental exploration. Experience of noisy trades shows that emotionally stable people are able to adjust to noise and cease to notice it within a day or two, though work now being undertaken by the Industrial Health Research Board may perhaps show that noise has an unfavourable influence upon output.

---

[1] THE LANCET, 1931, i., 852.

[2] 2me Congrès International de Pathologie Comparée, Paris, 31, vol. i., p. 68.

It appears then that people suffer from noise because they are nervous, which is a reversal of the assumption that noise produces nervous conditions. Nevertheless there are vicious circles in psychopathology, and though noise may be distressing because of the nervousness of the victim yet it may in turn exacerbate the nervous state. In the tendency to blame noise as a primary cause of nervous breakdown the psychopathologist sees, however, an unhealthy attempt—one among many—to avoid the recognition of the true nature of the complaints grouped under that convenient but obscurantist diagnosis. The chorus of popular approval that greets such blame marks the universal tendency to externalise inner difficulties of emotional adjustment to life, though it may be useful in furthering any movement for the suppression of noise—for noise, like a bad smell, is a nuisance from which we all, nervous or not, have a right to be protected.

ANNOTATIONS

CHEAPER AND QUICKER LAW.

BUSINESS men in London and elsewhere have long demanded that litigation in the High Court be made simpler, cheaper, and quicker. Certain definite suggestions were made, for instance by Mr. Claud Mullins in his book "In Quest of Justice." The two branches of the legal profession criticised the proposals collectively, and now the Rule Committee of the Supreme Court has evolved a "new procedure" for certain classes of not too complicated actions where the stages of litigation are capable of abridgment. A judge will take personal charge of an appropriate case at an early stage and will issue directions as to the documents required, the admissions of fact, the further particulars to be given, and so on. A "summons for directions" has long been a common feature of those early stages of litigation which are so much more tedious and expensive than the layman knows; but hitherto it has been too mechanical an incident. The medical profession will be specially interested in two new provisions: first, that there will be power for the judge to limit the number of expert witnesses, and secondly, that it will be possible to remit to a special referee any question involving expert knowledge—in particular, any question as to the nature, extent, and permanence of an injury alleged to be due to the negligence of a party. The referee's report will be available to both sides; they can agree to accept it in whole or in part without further expense and one can easily imagine circumstances in which it will in effect terminate the litigation. If it is not thus accepted, it will still remain on record for the assistance of the court (subject to criticism by expert witnesses at the trial) and it is to have such weight as the court thinks fit if experts differ and the judge has to decide between them. One can forsee good use being made of the medical practitioner in the character of referee. He will be almost an assessor, in some sort an official independent witness having the authority well-nigh of an arbitrator.

The new procedure is not universally applicable. It will not apply to allegations of fraud or to actions for defamation, malicious prosecution, false imprisonment, seduction, or breach of promise, but will be available otherwise for ordinary actions in the King's Bench Division, the plaintiff's solicitor having authority to certify his case as fit for the new method. It is an approximation to the commercial court practice where Mr. Justice Bigham and others did wonders in narrowing the issues and shortening the hearing. The judge will have a discretion to order trial with or without a jury. Here is a prospect of economy, for trial without a jury means shorter trial, and length of trial means increased expense. Endless appeals are another source of expense and delay. The parties may under the new procedure consent to forego the right of appeal to the House of Lords, thus being content with the decision of the Court of Appeal or they may agree to limit their appeal to questions of law only. Something, too, will be done to meet another grievance of business men by enabling the judge to fix the date of a trial. Apparently two judges will sit continuously in London to take "new procedure" cases; intermittent absence on circuit will therefore not upset fixed arrangements. Documentary evidence, it seems, will be developed and proof by affidavit facilitated, subject to the safeguard for cross-examining a witness in a proper case.

Some of these new provisions will apply also to proceedings in the Chancery Division and some of the new procedure, it should be added, is not entirely new. Individual judges have already managed to introduce features like the limitation of expert witnesses. No one can say how far the new procedure will realise the reformers' hopes until it has been tried on a large scale. Meanwhile it may be accepted as a sensible attempt in the right direction. It goes as far, probably, as reform can be carried without fresh legislation by Parliament.

PLEURAL EFFUSION AND TUBERCULOSIS.

IN a statistical study Dr. J. F. Bratt and Dr. G. Ingebrigtsen have published in *Acta Medica Scandinavica* (vol. lxxvii., fasc. iv., 1932) some interesting facts about idiopathic pleurisy. The patients had been treated in the 12-year period 1918–1929 in a hospital in Trondheim and 313 out of the 388 were traced in the spring of 1931. Practically all these cases were associated with a pleural effusion, and in more than 50 per cent. the febrile period lasted a month or more. The cases were, therefore, as a whole, more serious than the average case of pleurisy treated at home. As many as 124 patients (32 per cent.) could refer to some source of tuberculous infection, but the percentage was much higher among the cases of pulmonary tuberculosis coming under observation in the same period in the tuberculosis service of Trondheim, where 692 (52 per cent.) of 1181 tuberculous patients gave a history of exposure to infection. Dr. Bratt and

Dr. Ingebrigtsen do not, however, jump to the conclusion from these figures that a considerable proportion of the cases of pleurisy were not tuberculous. They confine themselves to the remark that "it would, therefore, seem that the tuberculous clinical material was considerably more exposed than the pleurisy material." Of the 313 persons traced in 1931, as many as 200 were found to be well. In the interval 13 had died of non-tuberculous diseases, and 100 had developed tuberculosis which in 40 cases had already proved fatal. In nearly every case tuberculosis developed within three years of the attack of pleurisy, and it would, therefore, seem that after this interval patients who suffered from idiopathic pleurisy have not much to fear in the matter of pulmonary tuberculosis. This disease broke out a little more frequently among the patients whose pleurisy had been associated with fever lasting more than a month than among those whose febrile period had been shorter.

THE ROYAL ACADEMY.

THE annual display at Burlington House has received this year but a half-hearted welcome from expert judges, who find in the exhibition, despite much competent work, a tendency to retrogression—to an over-reliance upon accepted methods and a distrust of modern ideals. Such criticism cannot be passed fairly upon a distinctly large number of the landscapes. There are scattered up and down the walls many pictures where close observation has resulted in broad effects, and where the display of technical accomplishment has not been made at the expense of a beautiful whole. And these canvasses have gained by the more moderate size generally adopted. But the portraits in many cases merit the judgment. The fault here, when it has occurred, must be shared by the public, especially in the case of presentation pictures. For the representatives of those who have commissioned the pictures usually desire, and are sometimes able to insist, that the rendering of the subject should follow their leading, which has to be taken as the view of the donors. All portraits painted on commission, to meet the pleasure of a heterogeneous group of subscribers, must run the risk of compromise, and it is unfair not to recognise this fact. Sir Arthur Cope's successful portrait of Dr. Alfred Cox has been painted in circumstances that safeguarded him from the risk, for the members of the selection committee were intimately familiar with Dr. Cox in every phase of his activities, and at any point were able to judge how far the picture represented the man and his works. The other important canvass in the exhibition, having a medical man for its subject, is the presentation portrait by Mr. George Harcourt of Colonel Thomas Sinclair, M.P. for Belfast, and emeritus professor of surgery in the Queen's University, having held the chair for nearly forty years. This is not such a challenging picture as Dr. Cox's portrait, because Dr. Cox is depicted in the robes of an LL.D., whereas Prof. Sinclair is in morning dress; but it is a thoroughly competent and sympathetic depiction.

OPIUM SMOKING IN THE FAR EAST.

THE recommendations of the Bangkok conference[1] came under the consideration of the Opium Advisory Committee of the League of Nations at Geneva on April 22nd. It will be remembered that the conference was concerned with the findings of a commission appointed by the League to visit the Far East and to report on the steps which had been, or should be, taken to fulfil the treaty obligations of 1912 and 1925 to restrict and suppress the use of "prepared" opium for smoking. The obstacle presented to such achievement by the extent of the illicit smuggling of opium was also to engage the consideration of the commission. Dissatisfaction was expressed at the failure to fix a time within which the prohibition of import and export of prepared opium, as prescribed by the Hague Convention, should be effected; nor indeed does it appear that a term has been set from which the period of 15 years' grace, conceded by the Geneva Protocol of 1925, was to commence. The delegates of Italy and China denounced the conference and its recommendations as tending to encourage rather than to restrict the sale of opium for smoking. The American delegate urged prohibition of commerce in "prepared" opium, and distrusted the proposal for Government monopoly in the drug. He was twitted by the British representative, who remarked that "prohibition" had not been altogether satisfactory in the States. The export of Indian opium for smoking, though undergoing an annual reduction of 10 per cent., again led to criticism that this was inconsistent with the principles of our dangerous-drugs legislation. Whereas heavy fines and imprisonment are meted out to those found in possession of opium for smoking in this country, considerable sales of prepared opium are still a source of profit to the Indian Government. Doubtless, smuggling from China and elsewhere continues to make the execution of a more stringent policy difficult, if not impossible, and the League's Far East Commission was probably right in saying "the radical method of dealing with illicit traffic in opium is by controlling effectively the cultivation of the poppy, allowing only such quantities to be produced, under international control, as are required for the world's medical and scientific needs."

SOCIOLOGICAL ASPECTS OF OBSTETRICS.

THE increasing interest being shown by obstetricians and gynæcologists in the sociological aspects of their specialty is reflected in the subjects discussed at recent meetings of the North of England Obstetrical and Gynæcological Society and the Edinburgh Obstetrical Society. At a meeting of the former society held in Liverpool on April 1st, Mr. Leyland Robinson, speaking on Insanity in Pregnancy, described his attempt to throw light on the problem by drawing up a questionaire from the obstetric standpoint and submitting it to a number of mental experts. In reply to the question whether child-bearing is an important factor in the ætiology of insanity, most of the alienists consulted failed to agree with the obstetrical view that pregnancy might exert a selective influence upon the mind of the pregnant woman. They attributed physical or mental stress rather to abnormalities of parturition, such as sepsis or toxæmia, with consequent exhaustion, than to the state of pregnancy itself. The following possible indications for the induction of abortion were given: (1) The onset of mania with great violence during pregnancy, since this might lead to dangerous exhaustion and it might be impossible to control the muscular movements. (2) The appearance of mental symptoms in a pregnant woman who had developed insanity during a previous pregnancy. (3) Mental disturbance founded on the conviction that death would ensue during labour, especially if associated with attempts at suicide or homicide. (4) Pregnancy combined with physical and psychical complications. There was little evidence that induction of abortion had any positive therapeutic value in arresting the development of permanent insanity. Mr. Robinson stated that the majority of answers he received were strongly against the induction of abortion on eugenic grounds—that is, for fear of mental deficiency in the offspring—and his general conclusion was that the effect of reproduction upon insanity has received little scientific attention and was for the most part unknown.

---

[1] See THE LANCET, 1931, ii., 1143; Feb. 6th, 1932, p. 299; March 12th, p. 581.

This conclusion is in accordance with the doubts expressed by Prof. Sydney Smith, addressing the Edinburgh Obstetrical Society on March 9th, whether conditions such as nervous debility, neurotic and psychoneurotic states which have been put forward as good reasons for inducing abortion really provide just cause for the operation in the present state of the law. What constitutes a just cause is a difficult matter, as there are no legal pronouncements on the point, but up to recent years medical men were of opinion that abortion should be carried out only when it was necessary in order to save the life of the mother or to prevent serious impairment of her health. Lately, he said, there has been growing up a considerable body of opinion which is disinclined to bow to the ethics of past generations, and individual knowledge regarding sex matters has been greatly increased. Prof. Smith gave statistics to show how great was the prevalence of abortion at the present time, and how impossible it was, in this country at any rate, to get correct figures, since only a very few cases of procuring of abortion come to light. In Germany, where there had been a steady fall in the birth-rate with a rise in the abortion-rate, there had been many discussions on the advisability of advocating the legalisation of abortion on grounds other than medical. In Russia the incidence of abortion was so great after the revolution in 1917, and the maternal morbidity and mortality so appalling, that the Soviet Government in 1920 authorised the operation in certain circumstances. In that country abortion might be carried out only by medical practitioners and in public hospitals, it still being a crime for any unauthorised person to interfere with pregnancy; before abortion could be induced, the woman must make application to a representative board before authorisation is granted. In the year 1924–25, 254,000 abortions were carried out in Soviet Russia, whereas in 1929 in Leningrad 58,000 abortions were registered, and only 39,000 births. In Russia it was found that abortions were desired principally by multiparous women, and not among women pregnant for the first time. Legalisation of abortion had caused a diminution in maternal morbidity and death; the number of patients entering hospitals for uterine hæmorrhage was decreasing steadily, and the number of cases of puerperal sepsis was also said to have decreased. The Departmental Committee on Maternal Mortality and Morbidity came to the conclusion that abortion played a serious part in the production of puerperal sepsis and in the causation of maternal morbidity and death. Prof. Smith considered that we could effect an immense saving in maternal life and health if we could prevent ignorant interference with pregnancy, and that this could not be achieved by repressive measures. In his view the law of abortion ought to be changed so as to allow unfortunate and desperate women to place their case before some authority who could, upon sufficient cause being shown, authorise the termination of pregnancy under decent conditions instead of as at present forcing her to place herself in the hands of an ignorant abortionist. The opponents of this view would doubtless hold that those who furtively disobey the law must take the consequences, but if, as seems likely, the chances of permanent damage to the mother are very small where the operation is performed openly, the medical and eugenic indications for sanctioning abortion may have to be extended in the future to include the avoidance of mortality and morbidity.

THE SCIENCE OF EXERCISE.

IN our review columns this week two important works on the physiology of exercise are noticed both emanating from America, though one is a translation from the German. It is not surprising that most works on this subject and on physical culture in general are contributed by American writers, for the cult of physical development has been widely spread and fostered there. Chairs of physical education are endowed with the status accorded to other professorships, and elaborate courses of instruction are framed. Directors of physical education and hygiene—officials whose raison d'être has not yet been recognised in this country—join forces with physiologists and biochemists in a field of investigation where material and opportunities are unlimited. The lack of such subsidised and organised research must not belittle the importance of British activities. One has only to recall the pioneer contribution by Fletcher and Hopkins on lactic acid metabolism. The late Prof. F. A. Bainbridge's "Physiology of Muscular Exercise," published in 1918—the third edition of which was admirably rewritten in 1931 by Bock and Dill of Harvard—has served as an inspiration to all authors of subsequent text-books along the same lines. The classical work of Starling on the heart and of Haldane, Douglas and Barcroft upon respiration, is generally regarded as of supreme authority. Of more recent date A. V. Hill and his co-workers have been conspicuous in their fascinating experiments with Human Machinery, particularly in relation to the subjects of oxygen debt and the viscosity of muscle, while Adolphe Abrahams has been the exponent of what might be regarded as the clinical side of the subject. The liberality with which these British workers are quoted is ample testimony to the authority with which their results are invested. But interest in the theoretical side of athletics has not been so universal as in other countries, and it is time that the problems of physical education had a larger share of attention in academic circles.

THE HAMBLEDEN DEPARTMENT OF ANATOMY AT KING'S COLLEGE.

THE signs of closer amity between the various schools of the University of London were noted by the Earl of Athlone when, as Chancellor, he opened the new anatomy department of King's College which is [illegible]ed after the late Lord Hamblede [illegible] to something a little sharper than friendly rivalry in the relations which at one time existed between King's College and University College was received with amusement, and his expression of the eager coöperation now achieved with appreciation. The department, he said, would stand as a witness of how closely interwoven were the schools of the University; medical students would pass on to King's College Hospital, Charing Cross, St. George's, or Westminster. Mr. W. R. Halliday, LL.D., principal of King's College, said that it was largely owing to the wise guidance as well as to the generosity of the late Lord Hambleden that the College survived a crisis when its very existence was threatened, became incorporated in the University of London. and entered its present phase of steadily increasing responsibilities and usefulness. The major problem of accommodation had been that of the part of the College known as the south-east block, in which anatomy and chemistry existed in cramped and unsuitable quarters. The generosity of the London County Council to the University had enabled the Court to make substantial contribution to the cost of the new department, and to the completion of the first half of the building scheme. The second half of the scheme would be pressed to the earliest possible conclusion as far as funds allowed. The space now vacated by anatomy would have to be remodelled partly to effect improvements in the chemistry laboratories, and partly to provide more adequate common room and refectory facilities for students. The College had acquired a lease of 21, Surrey-street, the corner house facing the Embankment, where chemistry research laboratories would be grouped together and connected with the rest of the department by a bridge like that between the east wing and the north end of the College. The Principal was convinced that the decision against the removal of the College to another site was a wise one, and the dignity of the present buildings would certainly have been difficult to achieve in any other quarter of London. There was general agreement among those present with the Chancellor's praise of the manner in which two storeys had been added to the College building without interfering in any way with the æsthetic appearance of the quadrangle and Somerset House.

TUBERCLE BACILLI IN THE BLOOD.

THE cultivation of tubercle bacilli from the peripheral blood has been brought into prominence during the last two years by Prof. E. Löwenstein, of Vienna, and the two papers by Dr. Cicely Weatherall and Dr. J. N. Cumings, printed at the front of our present issue, are valuable contributions to the subject. Weatherall has first of all tested various methods of culturing the washed hæmolysed stromata of the blood of infected guinea-pigs in a synthetic fluid medium, on Dorset's egg, and on egg medium enriched by glycerin veal broth; for a portion of her tests she used the blood technique of Löwenstein as modified by Dr. H. Moos Schwabacher, who has reported successful results in advanced pulmonary tuberculosis. Weatherall has also made a series of cultivation experiments on the blood of sanatorium patients, most of whom were sputum-positive, and in no case did she succeed in cultivating the tubercle bacillus, though one successful result was obtained at a later stage by the use of Dreyer and Vollum's deep veal broth culture method with tuberculous guinea-pig's blood. Dr. Cumings also reports negative results in attempting 25 blood cultures from patients in which the Löwenstein technique was employed for preliminary treatment of the patient's blood before planting. So far as we are aware, therefore, the only positive results obtained up to the present time in this country with the Löwenstein technique are a small series described by Dr. Moos Schwabacher [1] and by Dr. K. Eckenstein on her behalf.[2] It should be emphasised that the Löwenstein technique consists in two operations: (1) the use of a special method of obtaining a dark brown residue from the blood withdrawn from the patient's vein, by hæmolysing the blood with weak acetic acid and treating with dilute sulphuric acid to destroy contaminants; and (2) cultivating this hæmolysed blood residue on a special egg medium to which potato, asparagin. and Congo-red have been added. This medium was described in our columns last year (1931, i., 1147). Various workers. including Weatherall and Cumings, have departed from the original technique in some details. such as the choice of media, so that the results are not in absolute strictness comparable with those of Löwenstein in Vienna; but they support the figures of some other workers in different parts of the world in that they do not confirm the Löwenstein results. These results may be regarded from two different angles: first, there is the high percentage of positive blood cultures obtained from patients known to be tuberculous; and, secondly, the positive cultures obtained in cases which are generally considered far removed from tubercle, such as acute rheumatism in childhood, disseminated sclerosis, and retrobulbar paralysis. As to the first point, the percentage of positives in known tuberculous patients is considerably higher than is found with the older guinea-pig test, and raises the question propounded by H. C. Sweany and M. Evanoff[3] in America, whether, after all, the culture medium may be more sensitive than the guinea-pig. With uncontaminated material this may conceivably be so, but there are pitfalls in the shape of acid-fast bacilli of feeble virulence, and of acid-fast saprophytes which we believe are by no means as uncommon in occurrence as has been supposed; indeed, one of the most interesting by-products of the work of Löwenstein, Sweany and Evanoff, and others, seems likely to be a wider clinical recognition of these organisms. From the point of view of the pathology of tuberculosis also, the old question is raised anew by Löwenstein's work: what is the nature of the tubercle bacillæmia? Are the bacilli discharged into the blood stream in an intermittent embolic fashion, or are they steadily persistent throughout the circulating blood? Are they present in all types of tubercle at all stages of the disease? We are not yet within sight of an answer to this important question which the new radiological-pathological aspect of X ray film interpretation is rendering highly controversial. As to the second point, it must be borne in mind that Vienna has a high tuberculosis incidence, and we must not expect necessarily to be able to reproduce Löwenstein's figures in this country. The difficulty is to account for the presence of true tubercle bacilli in some of the diseases in which he has found them, and at the same time for their absence, as he records, in healthy persons.

WATER METABOLISM IN EPILEPSY.

IN a leading article a month ago[4] it was pointed out that although artificial dehydration may abolish fits in the epileptic subject, and water retention may produce them, it does not by any means follow that water retention is directly responsible for the spontaneous convulsion. Dr. F. B. Byrom,[5] from a study of the total exchange of water. sodium, potassium, and nitrogen during the different phases of epilepsy, concludes that the spontaneous convulsion is preceded by no changes detectable in 24-hourly measurements of these substances. The convulsion is. however, attended by a marked loss of body-weight, attributable to an extrusion of body fluid principally by the kidneys and to a lesser extent by the skin, a finding which confirms the observation of J. L. Gamble and B. Hamilton (1927), who showed that in epileptic children the excretion of sodium rose during the period of the convulsions, and concluded that this indicated a loss of extracellular water at this time. While it may at first sight seem difficult to reconcile Byrom's findings with those of I. McQuarrie (1929), who showed that ingestion of large amounts of water will precipitate convulsions in epileptic children (especially if diuresis is prevented by injection of pituitrin), he points out that such procedures cause not only change in bulk of body fluid but also secondary derangement of water-electrolyte balance. Indeed, when saline was substituted for water, McQuarrie found in subsequent experiments that convulsions were no longer produced when the fluid was retained. It may reasonably be deduced that the epileptic convulsion is not, as was at one time suggested, directly dependent on the degree of hydration of the body tissues, and that future research along these lines will be more concerned with possible local changes in water-electrolyte equilibrium.

A CASUALTY DEPARTMENT FORTY YEARS AGO.

Sir D'Arcy Power, in the Finlayson memorial lecture which he delivered recently at Glasgow, described the surgical side of the casualty department at St. Bartholomew's Hospital when it was in charge of Mr. C. B. Lockwood and himself in 1898. It was housed, he said, in the large hall facing Smithfield which is now used as a dining-room for the nursing and domestic staff. One third of the hall was allotted to the surgical and the rest to the medical casualty patients. The entrance to the hall was by six easy steps which led from Smithfield through two half-glazed doors. On the opposite side of the hall and exactly facing these doors was a small dispensary provided with counters and shut off by sash windows. The dispensary so closely resembled the bar of a public-house that many a drunken man was easily persuaded to take a double dose of house physic thinking it was a last glass before going home. It contained stock medicines brought over from the apothecary's shop in brown stoneware jugs holding 2, 4, 6, 8, and 12 gallons apiece. This dispensary was presided over day and night by two nurses—for many years by a mother and daughter of enormous size and weight known to generations of dressers as "the Fairies" because they moved lightly, were never out of temper, ill, or away from duty. They were untrained and were replaced in due course by "Sister Armitage" a highly skilled nurse and a magnificent organiser who had the power of subduing the most noisy and turbulent woman by sheer force of her personality.

The routine of the surgery was invariable. The patients began to assemble on the steps in Smithfield about 8.30 A.M., but whatever the weather there was no shelter and the doors were kept locked until the last stroke of nine. The assistant surgeon on duty entered the hall at five minutes to nine and saw that a porter had posted himself at the men's door and a nurse at the women's door. The two casualty physicians took their seats in the rooms allotted to them and the assistant surgeon stood with his back to the dispensary with the official whose duty it was to mark the time of arrival of the house surgeons and dressers. A queue, or rather a crowd, had assembled by this time on the steps and on the pavement. The man who sold bottles and ointment pots to those who had forgotten to bring them and the woman who was reputed to buy confection of senna and linctus for her open jam tarts, and the cod-liver oil for use in her neighbours' lamps, were in their places in the gutter ready to trade. At the last stroke of nine each door was held ajar to admit one patient at a time. The porter on the male, and the nurse on the female side, asked each patient what he or she complained of and referred him to the physician or surgeon as was thought fit. The diagnosis was rough and unskilled but was usually correct. Patients coming for the first time were directed to seats on either side of the dispensary where they waited until the assistant surgeon had interviewed them; those who had been treated previously took their places in a different part of the hall until they could catch the eye of the dresser under whose care they had been placed by their house surgeon. The prescription paper of each surgeon being of a different colour they were easily differentiated. The hall was usually filled by ten minutes past nine and the junior assistant surgeon having ascertained that the junior house surgeon on duty was present with his eight dressers, and that the senior house surgeon on duty was, at any rate, breakfasting, went to the benches where the new surgical patients were sitting. He made a rapid diagnosis, asked a few pertinent questions, and sorted them roughly into trivial, teaching, and serious. Patients with trivial complaints were handed over to the house surgeon who allotted them amongst his dressers; cases useful for teaching were sent over to the out-patient room there to await the arrival of the assistant surgeon of the day at 12.30; those who were seriously ill were taken straight into a ward. A fresh batch of patients was admitted from the street as often as the benches in the hall were empty until the clock struck ten. The outer doors were then closed though the morning's work often continued until midday or even later. By this time on a damp and foggy morning the atmosphere of the hall was poisonous and the odour pungent.

Bad and wasteful as was this condition of things, it was worse on the medical side. Dr. Robert Bridges, afterwards Poet Laureate, says that he saw and prescribed for 7735 persons during his year of office in 1877, and that 5330 of these were new patients. The average time spent on each case was 1·28 of a minute, and he congratulated himself on having given a separate audience to the troubles of 150 talkative women in three hours and a quarter. An even more wholesale method had been adopted a few years earlier. Mr. Frederick Wood, who was resident apothecary to the hospital from 1847–68, used, it is reported, to go into the hall at nine o'clock daily. As soon as the crowd was assembled and silence had been secured he would invite "all those with a cough stand up," and to them he gave a small cardboard ticket to be exchanged for a bottle of medicine at the dispensary. In like manner "all those with the bellyache stand up," and each received a ticket for house physic or castor oil. Long practice had enabled him to make a fairly correct diagnosis and he used to say with justifiable pride that, so far as he knew, he had never overlooked a case of strangulated hernia or of intestinal obstruction.

The whole system is now swept away. The King, as Prince of Wales, in 1907 opened a block of buildings in which the casualty department is adequately housed in a well-lighted and well-ventilated hall provided with suitable accommodation for male and female patients; in 1914 a corps of efficient almoners was appointed; in 1921 payment was demanded from those who were not absolutely destitute, and a "follow-up" system was introduced in 1922. Since February, 1923. each patient has been interviewed, with the result that there has been a fall in the attendances from 175,000 to 65,000.

THE PRIME MINISTER'S EYESIGHT.

THE Prime Minister has entered a nursing-home for an operation upon his right eye. The condition of the left eye continues satisfactory, but an examination of the right eye undertaken on his return from Geneva by his previous advisers. with the assistance of Sir John Parsons and Sir William Lister, led to the definite opinion that operation upon the right eye should not be further delayed. The condition from which he is suffering has followed the expected course. It has been realised for some time that, sooner or later, operation on the right eye would be necessary, and the choice of the moment to deal with this eye has been dictated not so much by any urgency in the symptoms as by the desire to fit in with the Prime Minister's public engagements.

RELIEF OF THE FAMILY MAN.

ON April 29th and 30th, at a conference promoted by the Family Endowment Society at the London School of Economics, an impressive case was put forward for a reform of our method of payment for work done. The subject was approached from both the economic and the biological aspect, and the speakers included Sir William Beveridge, Prof. Gilbert Murray, Miss Eleanor Rathbone, M.P.. Mr. R. A. Fisher. F.R.S., and Prof. Julian Huxley. It was shown that much greater progress has been made towards the desired object in many European countries, and in Australia and New Zealand, but that a patchwork beginning has been made in Britain. Put briefly. the aim is to replace the present system of equal pay for equal work, irrespective of family responsibilities, by one based on the principle of an equal standard of living for equal work, and to apply this principle not only to manual workers and artisans, but also to civil servants. members of the teaching professions, ministers of religion, and all salaried employees. At present, in this country the so-called "living" wage is supposed to maintain a man. his wife, and three children, and under this system a large proportion of the children are left below a reasonable standard of living. Three methods of financing family allowances were discussed at the conference. Family endowment paid for out of general taxation is impossible under present financial circumstances, though New Zealand makes allowances for children in excess of two in the family, when the income falls below a certain level. In Australia the tendency is towards a second method of fixing a basic wage for the maintenance of man and wife, and supporting the children by a levy on the employers of a certain percentage of the wages bill. This method. strengthened by "equalisation pools," so that an employer loses nothing by employing married men, is making rapid and continuous progress in France and Belgium. A third method is to extend the compulsory contributory insurance system to family endowment, and a scheme was described under which a weekly contribution of 9*d*. each by the employer. employee. and the State would produce an adequate maintenance allowance for the children. The conference was attended by a large number of representatives of bodies interested in social welfare, many of whom were evidently surprised to hear of the progress made towards family endowment in other countries. From the eugenic aspect it was pointed out that the scales are at present heavily weighted against parenthood. except in the case of the reckless section of the population. and that family endowment would gradually remedy the differential birth-rate by discouraging undesirable birth control on the one hand, and by tending to make responsible citizens of the reckless on the other. To those who might think the present time is inopportune for new schemes, it was pointed out that wages and cost of living are both changing and that, when "cuts" are restored. the family allowance system might well be considered. The case of the teachers was specially mentioned. Sir William Beveridge in his opening remarks emphasised family endowment as the best means of abolishing poverty and mentioned that all politicians paid it lip-service and professed approval. The Family Endowment Society (52. Romney-street, S.W.1) has much information in pamphlet form for those who wish to study this question. which all public health workers must regard as one of front-rank importance.

THE next session of the General Medical Council will commence at 2 P.M. on Tuesday, May 24th; under the Presidency of Sir Norman Walker.

THE Linacre lecture is being delivered at Cambridge to-day, Friday, May 6th. by Dr. J. J. R. Macleod, F.R.S.. Regius professor of physiology in the University of Aberdeen. His subject is the Control of Carbohydrate Metabolism.

IN the report of the National Physical Laboratory for 1931. reference is made to many activities which have a bearing on medical problems. Among the most important of these is the inspection of X ray departments in hospitals to ensure the safety of workers. This service is said to be widely used and appreciated. The laboratory is responsible for the custody of the radium belonging to the National Trust, and this work involves careful record of the history of the units into which the radium is divided. The difficulties relating to the establishment of an international unit of X rays (the Röntgen), which is essential for the advancement of X ray therapy, have now been resolved.

Sir William Wheeler, past President of the Royal College of Surgeons in Ireland, has accepted the invitation of the board of regents of the American College of Surgeons to deliver the Murphy oration in surgery at the opening meeting of the clinical congress, to be held in October next. The first John B. Murphy oration was delivered by Sir Berkeley Moynihan in 1920. and he was followed in subsequent years by Dr. William J. Mayo, Prof. Raffaele Bastianelli. Dr. George W. Crile. Drs. N. D. Royle and John L. Hunter. Sir Arbuthnot Lane, Prof. Archibald Young. Sir John Bland-Sutton. Prof. Vittorio Putti, Prof. D. P. D. Wilkie. Prof. G. Grey Turner, and Prof. A. H. Burgess.

THE Minister of Health. with the approval of the Prime Minister. has appointed Sir Arthur Lowry to act as Deputy Secretary to the Minister of Health. while Sir Ernest Strohmenger is seconded for service in the Treasury.

SPECIAL ARTICLES

UNDULANT FEVER PRODUCED BY BRUCELLA ABORTUS:

THE POSSIBILITY OF INFECTION FROM MILK AND THE PROBABLE EXTENT OF INFECTION.

By C. P. Beattie, M.B. Edin., D.P.H.,
SPECIAL ASSISTANT IN THE BACTERIOLOGY DEPARTMENT OF THE UNIVERSITY OF EDINBURGH.

Much interest has recently been shown in the reports of cases of undulant fever in this country due to the *Brucella abortus*.

The first possible mode of infection is through direct contact with animals harbouring the organism. Farmers, veterinary surgeons, abattoir workers, and employees in the meat-packing industry may be thus infected. This is generally agreed to be the most potent source of infection and numerous cases have been reported from the United States and the Continent (Orr and Huddleson,[1] Kristensen,[2] Bierring,[3] Dubois and Sollier [4]). The proportion of the population of this country, however, exposed to this risk must be small.

The second possible source of infection, the drinking of milk containing this organism, must be regarded as the commoner, and it has been long known that *Br. abortus* localises in the udder of infected cows and may persist for long periods. Apart from the investigation of cow's milk in Manchester, carried out in 1926 by Wilson and Nutt,[5] little information has been available as to the proportion of milk in this country containing *Br. abortus*. An investigation into the prevalence of tubercle bacilli in milk carried out during the past year for the Department of Health for Scotland has provided the opportunity of inquiring also into the frequency of the occurrence of *Br. abortus* in market milk. The results obtained are of some value in amplifying the information already available.

The milk samples received were of three classes: pasteurised, "retailed," and "raw." The "retailed" milk was that sold in dairies in the city of Edinburgh. In many cases the sample was a mixed one containing milk from more than one source. The "raw" milk was that delivered to dairies and each sample came from a single source.

Methods.—The centrifuged deposit from 50 c.cm. of milk was emulsified in 6 c.cm. of saline solution. Of this emulsion 3 c.cm. were injected intramuscularly into each of two guinea-pigs. For the purpose of the primary inquiry regarding the presence of tubercle bacilli the guinea-pigs were killed four weeks and eight weeks respectively after injection. In examining for *Br. abortus* the second guinea-pig was used.

The spleen of the animal was seared with a copper spatula and cultures made from it on serum agar plates. These plates were incubated for three days at 37° C. in a jar from which 10 per cent. of air had been exhausted and replaced by CO_2 (Smith,[6] McAlpine and Stanley,[7] Wilson [8]). Colonies resembling those of *Br. abortus* were then subcultured on serum agar slopes which were incubated for three days in an atmosphere with 10 per cent. CO_2. Films were made from these cultures, and if the organism present resembled *Br. abortus* it was tested for the absence of fermentation properties on glucose and its agglutination by *Br. abortus* antiserum.

The results obtained were as shown in Table I.

As the procedure of isolating the organism from the inoculated guinea-pig took some time and involved detailed cultural tests it was hoped to show that corresponding results could be obtained by demonstrating the presence of specific agglutinins in the guinea-pig's serum. The results of the tests were as given in Table II.

Table I.

Type of milk.	Samples examined.	Positive.	Percentage positive.
"Raw"	86	17	19·8
"Retailed" ..	83	29	34·9

Table II.

Type of milk.	Samples examined.	Inoculated animals giving positive agglutination results.	Percentage.
"Raw"	63	14	22·2
"Retailed" ..	56	19	33·9

The lowest titre accepted was a serum dilution of 1 in 120, but the agglutination titre was usually much higher (1 in 480 to 1 in 3200). On two occasions the end titre was only 1 in 120, but in both these cases the result was confirmed by the culture of the organism from the guinea-pig. For control purposes the sera of 66 animals which had been inoculated with pasteurised milk were examined. None showed any agglutination. In some, but not in all, cases the serum was tested twice; once unheated and once after being heated to 56° C. for 30 minutes in order to eliminate the possibility of non-specific agglutination.[12] The general effect of heating the serum was to cause a slight fall in the titre. The impression gained, supported by the findings in the sera of animals inoculated with pasteurised milk was that this precaution was unnecessary.

The percentages obtained by cultural and serological methods showed a fairly close approximation.

An analysis of the findings elicited the following discrepancies. From the guinea-pigs inoculated with "retailed" milk the organism was isolated in five cases when the serological test proved negative. In no case when the serological test was positive did culture prove negative. These results would appear to be in accord with the findings of Carpenter [9] in human cases of undulant fever due to *Br. abortus*. Out of five cases in which he recovered the organism by blood culture he succeeded in showing the presence of agglutinins in three only.

The results obtained among the guinea-pigs inoculated with "raw" milk were at variance with the preceding results. In this class agglutinins were demonstrated in three cases when culture failed. In every case when agglutinins were present the organism was obtained on culture.

The figures obtained show a high proportion of milk to contain the *Br. abortus*. By cultural method the percentage for raw milk was 19·8 per cent. and for retailed milk was 34·9 per cent. As has been explained some of the "retailed" milk samples were "bulked" specimens which accounts for the greater prevalence in this group. The proportion found is considerably higher than that reported by Wilson and Nutt [5] in Manchester in 1926: 5·7 per cent. of unmixed milk and 8·8 per cent. of mixed milk.

From the small number of samples examined no definite conclusion can be drawn as to the relative reliability of cultural methods in inoculated guinea-pigs and the demonstration of agglutinins in their serum. The indication is, however, that the demonstration of agglutinins in the serum of guinea-pigs is likely to afford a sufficiently reliable indication of the proportion of milk infected. It is a method which can readily be combined with the routine biological test for the presence of the tubercle bacillus in milk.

CLASSIFICATION OF STRAINS.

In view of the indications that the porcine type of *Br. abortus* is more pathogenic than the bovine variety (Huddleson and Hallman [10]) and that cattle may be infected with the porcine type (Plastridge and McAlpine [11]) it was decided to attempt to classify the strains isolated. Huddleson's dye plate method was used.[1]

In this method three nutrient agar plates are used, the first containing 1 : 100,000 parts of methyl-violet, the second 1 : 50,000 parts of basic fuchsin, and the third 1 : 50,000 parts of thionin. These will be referred to as V., F., and T. Typical reactions should be :—

—	V.	F.	T.
Bovine	+	+	−
Porcine	−	−	+++

The number of + marks signifies the relative amount of growth.

The results with 36 strains so tested showed them all to be of bovine type. Confirmation of this was found in the fact that during their first subcultures none of these strains grew freely under normal atmospheric conditions, but required a CO_2 concentration of 10 per cent. For control purposes nine bovine and six porcine strains obtained from the National Collection of Type Cultures were tested and found to give the reactions characteristic of their type.

The possibility of infection from a milk-supply in which over 30 per cent. of unsterilised mixed milk contains *Br. abortus* is obviously great.

DISCOVERY OF CASES.

It was thought that some indication of the prevalence of *abortus* infection would be obtained by examining blood samples sent to the laboratory for the routine Widal examination, such samples coming from patients whose symptoms were those of a continued fever. The blood was obtained partly from the city of Edinburgh and partly from the neighbouring counties.

Twenty-eight specimens from the city were examined. Of these, five agglutinated *Br. abortus*. The agglutination titres were: Case 1, 1 in 240; Case 2, 1 in 480; Case 3, 1 in 960; Case x, 1 in 240; Case 4, 1 in 6400. Two further samples agglutinated *Br. abortus* in a dilution of 1 in 30, but this was considered within normal limits. Three of the samples examined gave a diagnostic reaction with *B. paratyphosus* B. In none of these was agglutination of *Br. abortus* obtained.

Forty-seven specimens from the surrounding counties were examined. Of these, two agglutinated *Br. abortus* in high dilutions. The agglutination titres were: Case 5, 1 in 2500; Case 6, 1 in 1920. Four samples gave agglutination in a titre of 1 in 30, but as stated above this is not a significant result. Eight of the specimens submitted gave a diagnostic reaction with *B. typhosus*, two with *B. paratyphosus* B, and one *B. dysenteriæ* (Flexner-Y). None of these agglutinated *Br. abortus*.

The following data obtained from medical men in charge of the cases are illustrative.

CASE 1.—Oct. 28th, 1930. Male, aged 45. Tailor. Chief symptoms: severe headache and sweating, general body pains, high temperature without remissions. Duration of illness six weeks. Widal reaction negative. *Br. abortus* Bang (emulsion of live organisms) agglutinated by serum 1 in 240. This case was at first considered one of influenza.

CASE 2.—May 19th, 1931. Nurse, aged 54. Onset insidious, occipital headache, pain in back of head and neck, shivering in forenoon once at commencement of illness, spleen and liver not enlarged. Crepitations at bases of both lungs. Pulse-rate 88. Morning temperature subnormal; evening, 101° to 101 6° F. Ill for one month and in poor health for six to eight weeks thereafter. Drank unpasteurised milk daily but not in large quantities. Widal reaction negative. *Br. abortus* Bang (emulsion of live organisms) agglutinated by serum 1 in 480.

CASE 3.—June 9th, 1931. Illness resembled a sharp typhoid infection and was followed by a long convalescence. Widal reaction negative. *Br. abortus* Bang (emulsion of live organisms) agglutinated by serum 1 in 960.

CASE X.—Jan. 1st, 1932. Boy, aged 11. Diagnosis established of broncho-pneumonia. Widal reaction negative. *Br. abortus* Bang (emulsion of live organisms) agglutinated by serum 1 in 240.

CASE 4.—Feb. 29th, 1932. Male medical student, aged 25. Onset sudden. Frequent rigors. Temperature down in morning, up in the early afternoon, down in the late afternoon, and up at night, 101·8° to 102° F. Considerable sweating at night. Severe frontal headache at night. Pulse-rate 88. No backache, no joint or muscle pains. Spleen and liver not enlarged, no chest symptoms, constipated since onset of illness.

Never drank milk by itself but took it in tea and coffee. Had worked with cultures of *Br. abortus* some years previously. Was in U.S.A. during summer but returned in September, 1931. Had no illness while in U.S.A. Only previous illness bronchitis two years ago. Widal reaction negative. *Br. abortus* Bang agglutinated by serum 1 in 6400, *Br. abortus* (hog 900) 1 in 800, *Br. melitensis* Arkwright 1 in 800, *Br. abortus* Barker 1 in 6400. (Emulsions all phenolised.)

Blood culture, March 3rd, 1932, 5 c.cm. blood inoculated into each of two flasks containing 50 c.cm. Stafseth's liver infusion broth.[14] One flask incubated for seven days in *atmosphere of 10 per cent.* CO_2. *The other incubated for* seven days under ordinary atmospheric conditions. At the end of this time the flask which had been kept under atmospheric conditions showed no growth. The flask which had been incubated in 10 per cent. CO_2 was contaminated by an aerobic sporing organism. It was discarded. The flask which had been incubated under normal atmospheric conditions was now incubated for a further seven days in 10 per cent. CO_2. The organism was then isolated. On subculture it would not grow under ordinary atmospheric conditions but required a concentration of 10 per cent. CO_2. On Huddleson's dye plates it gave the reaction of a bovine type. The blood for this examination was taken during an apyrexial period.

Urine culture, March 3rd, 1932. Method as above—organism not isolated.

Clinically this was an undoubted case of undulant fever and the diagnosis was confirmed by the bacteriological examination. The source of the infection is not clear. His stay in the United States of America and his handling of *Br. abortus* might seem too distant to be related to the illness. He had no previous illness which might have been a previous attack. This case was first diagnosed as influenza and later, when the temperature did not abate, as paratyphoid fever.

CASE 5.—March 3rd, 1931. Male, aged 38. Engineer. Onset insidious. When first seen by doctor had been unfit for two months. During this time complained of afternoon fatigue and night sweating. When seen complained also of pain in joints and in calves of legs. Had a cough. Temperature showed marked daily remissions—evening up to 103° F. Pyrexial attacks showed an average period of ten days with two-day remissions between attacks. Liver and spleen not enlarged. Constipated. Condition looked better than temperature warranted. Drank large quantities *of unpasteurised milk. Widal* reaction negative. *Br. abortus* Bang agglutinated by serum 1 in 2500, *Br. abortus* Barker 1 in 2560, *Br. abortus* T 1 in 1280, *Br. melitensis* Arkwright 1 in 160 (emulsions all of live organisms). Blood culture negative.

CASE 6.—June 25th, 1931. Male, aged 36. Soap-worker. Onset insidious. Duration of illness, 12 weeks. Intermittent headache, backache in left lumbar region, no joint pains, no pain in calves of legs. Rigors during first few days but not thereafter. Afternoon fatigue, night sweating. Temperature: generally raised in the evening and down in morning. Pulse-rate: generally increased. Cough: slight congestion at base of left lung. Skin rash chiefly in iliac regions. Was away from home during the month prior to onset of illness. Widal reaction negative. *Br. abortus* Bang (emulsion of live organisms) agglutinated by serum 1 in 1920.

The number of cases is too small for accurate deductions, but would seem to indicate that a definite proportion of illness which gives rise to the suspicion of enteric fever is undulant fever. If the three cases of paratyphoid B infection and Case x, diagnosed as broncho-pneumonia, are excluded from the city of Edinburgh series, it is found that out of 24 cases of suspected enteric four were cases of undulant fever. Similarly if from the series outwith the city the cases of enteric and dysentery are subtracted, it is found that out of 36 cases two were cases of undulant fever.

No inquiry has yet been carried out in the Edinburgh area as to the percentage of persons not suffering from a febrile illness who give agglutination reactions with *Br. abortus*. A comparison may, however, be made with the figures obtained by Cruickshank and Barbour [12] in Glasgow last year. Of 1522 sera examined they found 25 (or 1·6 per cent.) gave agglutination in a dilution of 1 in 20 or over and 11 in a dilution of 1 in 40 to 1 in 80.

TWO OTHER CASES.

Two cases occurring in the city of Edinburgh during the period under review, but not included in the above series, were investigated also in this laboratory by Dr. H. J. Gibson. In these the main features were:—

CASE 7.—Jan. 7th, 1931. Male, aged 34. Rubber worker. Condition discovered during examination for life insurance. Temperature found to be 102° F. but felt well and was working. Previous week had shivery attack once in late forenoon. After Jan. 7th feeling of chilliness about midday. Afternoon fatigue, night sweating. Evening temperature up to 102° F. Pyrexial periods of five to seven days with one or two day intervals. Bronchitis at commencement. No arthritis. Constipated. Spleen not enlarged. Duration of illness six weeks. No relapses. Widal reaction four weeks after onset, negative. *Br. abortus* Bang (emulsion of live organisms) agglutinated by serum 1 in 3200. Blood and urine culture negative. No contact with animals. Home milk-supply pasteurised. Nineteen days prior to onset spent a day in Lancashire and drank raw milk there. (Case reported by Wishart and Gibson.[13])

CASE 8.—Sept. 6th, 1930. Male, aged 29. Customs officer. Onset: shivering attack while on motor-cycle tour. Severe headache, generalised pain in back and limbs. Remained indoors for a week; considered it influenza; did not see doctor. Recommenced work; morning felt fit, late afternoon chilliness, afternoon and evening feverish and unfit. Severe night sweating. Worked for two weeks and then saw doctor. Temperature when seen by doctor at evening surgery 104° F. Stiffness and pain on movement of shoulders and knees; muscular pain, especially in calves of legs. Night sweating severe throughout. No chest symptoms, no enlargement of spleen. Temperature: daily remissions. Evening, 99·2° F. to 100° F. Period of one week high temperature followed by two day remission, then two weeks high temperature followed by eight day remission, then one week high temperature. Widal reaction, seven weeks after onset, negative. *Br. abortus* Bang agglutinated by serum 1 in 240. A week later *Br. abortus* Bang 1 in 480, *Br. abortus* porcine type 1 in 200 (emulsions all of live organisms).

During work in docks dealt with imported bacon and scrap pork, but rarely, if ever, touched the meat. Home milk-supply pasteurised. In Glasgow, 27 days before onset, drank raw milk.

CASE 9.—August 13th, 1931. Male, aged 28. Medical man. A worker in this laboratory became infected with the disease. For four weeks he had felt unfit but continued at work. On August 13th his serum was examined and found to agglutinate *Br. abortus* Bang up to a titre of 1 in 1600. Widal reaction negative. His illness was typical and of a severe form, and he suffered during convalescence from arthritis of one of the small joints of his hand.

On August 28th *Br. abortus* Bang agglutinated by serum 1 in 1600. *Br. melitensis* 1 in 400. On Oct. 6th *Br. abortus* Bang 1 in 800. Convalescent. (Emulsions all of live organisms.)

Blood culture was performed on August 28th. 5 c.cm. blood inoculated into 50 c.cm. Stafseth's liver infusion broth [14] incubated for five days in atmosphere of 10 per cent. CO_2. Organism isolated. Grew readily under ordinary atmospheric conditions in subcultures. On Huddleson's dye plates gave reactions of porcine type.

In this case the source of infection was doubtful. He had been working with cultures of *Br. abortus* but not for some time prior to the onset of his illness.

That the organism may stimulate the production of specific antibodies without giving rise to illness is shown by my own experience. After working with infective material and cultures for ten months I found on August 13th that my agglutination titre for *Br. abortus* Bang was 1 in 320. On Jan. 18th, 1932, it was 1 in 400. On this date the serum of a laboratory assistant who had handled similar material to the same extent was examined. It gave no agglutination.

RESULTS OF THE INVESTIGATION.

The investigation is being continued and an endeavour will be made to determine what accessory factors are concerned in human infection. Although the proportion of raw mixed shop milk in Edinburgh containing *Br. abortus* has been shown to be about 35 per cent., only a very small number of cases of the disease have come to notice. The porcine strain of the organism is considered to be the more pathogenic to man, and in one of the two cases in which the organism was cultured it was of porcine type. But out of 36 strains cultivated from milk samples none would appear to be of porcine type. Plastridge and McAlpine [15] in an examination of 129 strains of *Br. abortus* from human sources found 63 to be bovine and 66 porcine. Taking into account the large amount of raw milk drunk and the comparatively small number of people handling pigs these figures would seem to be out of proportion to the chances of infection. Plastridge and McAlpine, however, justly point out that the porcine strain is more easily cultivated than the bovine. The relative virulence of strains isolated from milk have to be examined, and also the question of natural immunity.

As far as the investigation has gone it would seem to show:—

(1) That the possibility of infection from retailed raw milk is considerable. In Edinburgh 34·9 per cent. of such milk samples have been found to contain *Br. abortus*.

(2) That the test for the presence of *Br. abortus* agglutinins in the sera of guinea-pigs inoculated with milk provide a sufficiently accurate method of estimating the prevalence of *Br. abortus* in milk samples. This method can easily be adopted during the biological examination of milk for tubercle bacilli.

(3) That of 36 strains of *Br. abortus* isolated from milk in Edinburgh all were of bovine type.

(4) That a definite proportion of febrile illnesses which resemble enteric fever is undulant fever. In Edinburgh out of 24 such cases four were cases of undulant fever.

My thanks are due to those physicians in Edinburgh and neighbourhood who have permitted me to include their cases, to Dr. H. J. Gibson for the reports on Cases 5, 7, and 8, and to Prof. T. J. Mackie for his encouragement and advice. I also have to acknowledge the courtesy of the

Curator of the National Collection of Type Cultures in supplying me with strains of *Br. abortus*.

The work was assisted by a grant from the Moray Fund, Edinburgh University.

BRITISH ORTHOPÆDIC ASSOCIATION.

THE NOTTINGHAM MEETING.

AT the spring meeting of the British Orthopædic Association in Nottingham on April 22nd and 23rd, a large series of cases was demonstrated by Mr. F. CROOKS and Mr. MALKIN at the General Hospital and at the Harlow Wood Orthopædic Hospital, and three clinical problems were discussed.

Suppurative Arthritis of the Hip.

Mr. FREDERICK CROOKS (Nottingham) presented a series of 12 cases of pyogenic infection of the hip-joint. Early drainage was necessary, he said, not only to save life, but to minimise epiphyseal destruction. The classical route for drainage was by a posterior incision, but in half of the cases abscesses pointed in front of the joint and an anterior incision had been used. After operation the limb was fixed in abduction, and traction was maintained to prevent pathological dislocation. There was no mortality, and the end-result in 8 of the 12 cases had been a stable hip. In infants there was usually destruction of the epiphysis and of the neck of the femur, and often an unstable dislocation was inevitable.

Mr. D. MCCRAE AITKEN (London) advised a short spica and not a calliper as an ambulatory splint. In unstable cases the ring of the calliper pushed the neck of the femur out of the acetabulum and aggravated the tendency to dislocation. Operative stabilisation should be performed when the patient was 14 or 15 years of age by constructing a new roof over the upper end of the femur.

Mr. R. C. ELMSLIE (London) doubted whether any attempt at operative stabilisation was of value. The only measure he would advise was a bifurcation osteotomy, and although this stabilised the limb satisfactorily it had the serious disadvantage of increasing the shortening. The best end-result which could be secured was a bony ankylosis in good position.

Dislocation of the Patella.

Mr. S. A. S. MALKIN (Nottingham) reported seven cases of outward dislocation of the patella. In five cases the displacement was habitual and of congenital origin, and in two cases recurrent. Normally, in consequence of the erect posture of man, the oblique axis of the quadriceps maintained an angle with the vertical axis of the patellar ligament, and favoured outward displacement of the patella. This was still further exaggerated if knock-knee was present. Successful treatment demanded not only replacement of the patella, but realignment of the quadriceps with the patellar ligament; in congenital cases it was necessary to dissect and free the vastus externus, and in all cases it was advisable to displace the tubercle of the tibia inwards and downwards. The downward displacement compensated for under-development of the external condyle of the femur. If knock-knee was present, an osteotomy to correct it was essential, but the correction could be more easily secured in congenital cases by deferring osteotomy until after replacement of the patella and realignment of the quadriceps. The operation, which he had learnt from Mr. Elmslie, had been performed in six cases. After several years there had been no recurrence of the dislocation, and a normal range of knee movement was restored.

Mr. ELMSLIE said that the important features of his operation were (*a*) dissection and replacement of the vastus externus, (*b*) displacement of the tubercle of the tibia inwards and downwards, (*c*) transference of a pedicle of joint capsule from the inner to the outer side, (*d*) the construction of a flap of capsule to hold the rectus femoris inwards.

Mr. H. A. T. FAIRBANK (London) said that osteotomy of the femur was always necessary in habitual dislocation, but not always in recurrent dislocation of the patella. He had frequently noticed in recurrent dislocation that although there may be no genu valgum with the knee extended, this deformity was evident when the knee was flexed.

Fractures of the Spine.

Mr. CROOKS reported 44 recent cases of fracture of the spine. The mortality was 25 per cent., and in almost 50 per cent. of the cases the spinal cord had been injured. Reduction of the fracture was advocated, and emphasis was laid on the ill-effect of allowing patients to lie in bed for several weeks without active treatment. In such circumstances functional complications commonly appeared, and energetic exercises in the gymnasium were necessary to combat this. Twelve cases were demonstrated of crush fractures of the spine which had not been seen until several weeks after the accident, so that a slight kyphotic deformity remained. Although good movements were restored, only one of the 12 was free from pain, and only two had resumed work.

Mr. C. HOPE CARLTON (London) said that the results of treatment of crush fractures of the spine had been greatly improved since the introduction of the technique described by Watson Jones, but he had found difficulty in some cases in correcting the last few degrees of wedging of the vertebra.

Mr. W. A. COCHRANE (Edinburgh) said that he had used Watson Jones's technique in reducing fractures of the spine, but in two cases paralytic ileus had arisen, and he attributed this to the hyperextension, and the lack of abdominal support during reduction. The use of a ventral hammock assisted in preventing this.

Mr. R. WATSON JONES (Liverpool) drew attention to the constancy with which pain persisted, if the wedging of the crushed vertebra was not corrected. Records were now available of over 50 fractures of the spine which had been reduced by his method, and provided that the deformity was fully corrected and recurrence prevented by the wearing of a plaster jacket for a sufficiently long period, there was no pain, and fully 75 per cent. of cases resumed heavy work. Consolidation of fractured vertebræ was slow, and the plaster jacket should be retained in simple crush fractures for four months and in extensively comminuted fractures for six months. Energetic exercises could be practised throughout this time, and in uncomplicated cases recumbency was not necessary for more than a few days. Paralytic ileus might arise in any case where a plaster jacket was applied under anæsthesia, and was due not to the hyperextension, but to the anæsthetic and too liberal administration of morphine. No anæsthetic should be used.

Mr. S. Blundell Bankart (London) emphasised the necessity for immediate reduction. The pain of an unreduced crush fracture of the spine could only be relieved by operative fusion of the affected area with a bone graft. The best treatment for fractures of the lumbar transverse processes was to ignore the fracture and treat the case as a simple muscle injury, in order to avoid functional complications and to prevent adhesion formation.

Mr. W. H. Trethowan (London) said that persistent chronic backache was inevitable if crush fractures of the lumbar spine were not reduced. Since the pain was due to mal-alignment of the spine, he doubted whether bone grafting would always relieve it.

Mr. Naughton Dunn (Birmingham) advocated temporary splintage of the spine in order to decide whether bone grafting would be successful or not. Operative treatment could only succeed in those cases where pain was controlled by wearing a spinal support.

MEDICINE AND THE LAW.

A Doctor's Dog.

Not long ago the House of Lords dealt with a claim for damages where a dog, left in an otherwise empty motor-car, had leapt at a window and, by breaking the glass, had caused a passer-by to lose the sight of his eye. In effect their Lordships decided that the owner of the car had not been at fault, there being nothing against the dog's previous good character. A somewhat similar claim has been made against a medical practitioner who left his car outside Queen's Buildings, Scovell-road, Borough, S.E., with his Sealyham terrier tied up inside in such a way that its muzzle could protrude only 3 inches beyond the car door. Two children came out of an adjoining house and leaned over the car to look at the dog; one of the children was bitten, and damages were claimed in respect of her injuries. There was important evidence that children were in the habit of playing in the street at this place, that the doctor had warned them not to interfere with his car or tease his dog, and that the injured child had heard the warning. Even more important was the absence of any evidence that the dog was of a ferocious nature, either to the doctor's knowledge or at all. It was stated that the doctor had said "the dog might bite"; but this, as Mr. Justice Du Parcq observed, did not mean that the dog was ferocious; any dog may bite if interfered with, especially if guarding its master's property. At the trial of the action on April 15th the jury disagreed. Apart from the question of damages, if any, they were asked five questions. They were unable to agree in answering any of these except that they answered "No" to the question whether the child had been guilty of contributory negligence. The other unanswered questions were: (1) Was the dog of a ferocious disposition? (2) If yes, was the defendant aware of its ferocity? (3) Was the defendant negligent in leaving the dog tied up in the car? (4) If yes, was his negligence the cause of the child's injuries.

In these conditions defendant's counsel applied for judgment. He emphasised the absence of evidence of ferocity, and he contended that every car-owner is entitled to leave a dog to protect his car; if the dog is tied in such a way that it cannot bite passers-by but only persons who trespass by touching or entering the car, there is no breach of duty and no negligence. On the other side it was argued that the dog was a potentially dangerous thing placed on the highway where it was likely to be a temptation to children. The learned judge inclined to give some weight to this argument; a child, he said, might naturally be tempted to look more closely at a car with a dog in it than an adult would. "A dog cannot differentiate between a little girl, an inquisitive man, a thief, or a policeman who wants to make inquiries." It was possible that a jury might think the owner was therefore bound to take such precautions as to make an accident impossible. Consequently he could not give judgment for the defendant; the case must be treated as one in which the jury had failed to agree; in other words, the plaintiff is at liberty to bring the action over again.

Death Sentence on Youth of Eighteen.

During the last 40 years, said Sir John Anderson before the Committee on Capital Punishment, nobody under the age of 18 years has been executed in England. The Children and Young Persons Bill proposes to make this age-limit of 18 statutory. Jacoby was 18 years and 11 months when executed. One of the conditional recommendations of the Committee was that no one should be executed under the age of 21. Youth is, of course, one of the elements specially regarded by the Home Office in advising the commutation of the death penalty. In a recent case before Mr. Justice Travers Humphreys a youth of 18 was found guilty of murdering a girl of 6. Her body was found in a tin box; examination showed that she had been outraged and strangled with a cord. The accused's history showed abnormality. He was sent to a reformatory school at the age of 9 for five years, after attacking a child 2 years old whom he had left in a brook with his head cut open. The accused's paternal grandfather and maternal grandmother had been inmates of a mental hospital. His father said the boy showed no sense of causing pain or of fear, and had once put a cat down a street grid. Medical evidence, called on behalf of the defence, was to the effect that he was of the moron type, a rather higher-grade mental defective, subject to alternate periods of dullness and excitement. The witness who gave this evidence said that the crime must have been committed in a frenzy of sadistic lust. The judge told the jury that this was not a defence of insanity. The law, said the judge, provided nothing on the point of insanity concerning uncontrollable impulses. While this summing-up was strictly accurate, it may be remembered that the Atkin Committee on the Criminal Responsibility of the Insane (reporting after the case of Ronald True) recommended that the law should recognise irresponsibility on the ground of insanity where the act was committed under an impulse which the prisoner was, by reason of mental disease, in substance deprived of any power to resist. The Committee added that it might require fresh legislation to bring this principle into effect. No such legislation has, however, been passed; nor does the Home Office appear to have made much effort in this direction. In the recent case described above, Mr. Justice Humphreys stated that he should report to the proper authorities, who would take into account the question of the accused's age and of any abnormality in his mental equipment.

BRITISH HEALTH RESORTS.

THIRD REGIONAL CONFERENCE.

THE conference held last Saturday was the third of a series designed to bring together medical men and representatives of local interests to consider the medical values of the region. The avowed aims of the British Health Resorts Association which summoned it are briefly these; to formulate the medical case for the British health resorts in the prevention and cure of disease, to differentiate on a scientific basis the various regions and places, and to make this information known to the medical profession and the public. These aims were well achieved during the week-end when the municipal fathers of Weymouth, Poole, and Bournemouth afforded lavish opportunity for a study of the strip of coast from Hengistbury Head on the east to Portland Bill on the west. The headquarters of the Association were nominally at the Bath Hotel in Bournemouth, and the formal discussions took place at the Town Hall, but in point of fact the whole of the week-end was given up to a roving conference over this western section of the southern coastal region, in which the local health officers and practitioners played a leading part.

At the first of the two business sessions the tone was set by a remark contained in a letter from Lord Meston, chairman of the Association, who was detained at the League of Nations meeting: We have, he wrote, lived too long in an inferiority complex about our own health resorts. And Sir Thomas Oliver, who took the chair at this session, was well within the mark when he asserted that there are few islands with such an imposing coast-line and such attractive scenery as our own, the number and variety of the coastal resorts being unsurpassed in any country. This session was noteworthy for a remarkable analysis by Lieut.-Colonel W. Byam of the various reasons given to him by patients in refusing to stay in England when advised to do so. These reasons, in descending order of frequency, were: (1) Climate; (2) the English standard of cooking; (3) the unfashionableness of home resorts; (4) the need for a complete change of scene; (5) the lack of amusements; (6) the ban on gambling; (7) the greater cost at home; (8) the absence of facilities for a cure. Colonel Byam said he regarded the third excuse as really the most potent, for since it is the wives who decide where to go, a health resort must be fashionable. The fashionable crowd is, he added, a great attraction for the seekers after health. Others who took part in the discussion concentrated rather on item 8, being the absence of facilities for a cure. Dr. Fortescue Fox pointed out how far we are behind the continent in organising our resorts as centres of convalescence in the wider sense, for those commonly called convalescent constitute but a small group in comparison with those who are never really well or actually ill, but yet have a right to hope for complete recovery. It was this vast and increasing number of subnormal people, many of them doing the best work in the community, for whom the health resort should organise its facilities. Dr. Manson-Bahr raised the question of diet at the British health resort, which was the thing that bothered him. No one seemed to be capable of making liver soup for his patients. There was no one to supervise the diet in the case of (say) sprue, where treatment was almost entirely dietetic. His difficulty would be met if there was a local panel to whom he could apply for help and information. He and others were in sympathy with Colonel Byam's plea for a centre on this strip of coast where modern medical diagnosis and treatment could be carried out; a nucleus providing facilities to every practitioner in the district. For such a purpose London hospitals with their noise were becoming more and more impossible. Dr. R. A. Young called upon the local medical profession to tell him more of what in their experience were the indications for regional treatment, what patients they should send, and at what time of the year; for, he said, you have on this coast many varieties of climate within a small area, and what will suit residual catarrh will not be equally good for emphysema. On sending down a patient he would like to be able to say to him: You will get specialised treatment there for your cough, and there for your shortness of breath, and so forth. How happy he and his fellow-consultants would be to give an honoured place on their waiting-room tables to resorts willing to provide facts like these. Some of these difficulties were set at rest later by Dr. Watson Smith's assurance that the speakers had not realised what was already being done locally. Practitioners, he said, knew all about liver soup and even the Gerson diet—either could be provided like any other dietary at any time; and he added some definite information about the climatic qualities of places like Canford Cliffs and Swanage.

It is worthy of note that the conference definitely discarded any narrow or parochial policy. We have, said Dr. Alfred Cox from the chair at the afternoon session, to think regionally. There must be regional coöperation and no petty jealousies. Colonel Elliot, whose letter to the *Times* last September set the whole movement going, disclaimed any such policy. We are, he said, in no sense hostile to continental or other interests; we are willing to coöperate with the foreigner if he is willing to coöperate with us. And at the great banquet the deputy-mayor of Bournemouth, Alderman C. H. Cartwright, speaking for all the resorts represented, said they did not claim patronage on grounds of patriotism; they wanted the public to go to British resorts because they preferred them. This led some of the consultants present to put in a plea for the large number of patients who cannot afford the tariff of an expensive hotel. There is an impression, all too well founded, that they can get better value for their money at many continental resorts than they do in this country. This again may be no more than a question of collating and supplying information about the accommodation available for all classes of the community and for every length of purse.

Finally, the outcome of the afternoon session was the unanimous adoption of a resolution to form a local branch of the British Health Resorts Association for the southern region, western section, nominations being received of both medical and lay members from Christchurch, Bournemouth, Poole, Swanage, and Weymouth. The mayor of Bournemouth, Alderman P. M. Bright, J.P., consented to act as convener.

BOLINGBROKE HOSPITAL, WANDSWORTH COMMON.—The old portion of this hospital is reported to be "daily becoming worse"; the main kitchen, dining and sitting-rooms, and servants bedrooms are gloomy and dilapidated. Rebuilding will cost £70,000, towards which the King's Fund has promised £1000. To tide over some of the difficulties temporarily Sir James Carmichael, the chairman of the board, has undertaken to defray the entire cost of an extensive scheme of improvement. Last year there were 2373 new in-patients and 13,495 new out-patients. The total weekly costs of the in-patients was £3 0s. 9d. and the total cost of each occupied bed £158 9s. 9d.

crush fractures for four months and in extensively comminuted fractures for six months. Energetic exercises could be practised throughout this time, and in uncomplicated cases recumbency was not necessary for more than a few days. Paralytic ileus might arise in any case where a plaster jacket was applied under anæsthesia, and was due not to the hyperextension, but to the anæsthetic and too liberal administration of morphine. No anæsthetic should be used.

Mr. S. **BLUNDELL BANKART** (London) emphasised the necessity for immediate reduction. The pain of an unreduced crush fracture of the spine could *only be relieved by operative fusion of the affected* area with a bone graft. The best treatment for fractures of the lumbar transverse processes was to ignore the fracture and treat the case as a simple muscle injury, in order to avoid functional complications and to prevent adhesion formation.

Mr. W. H. **TRETHOWAN** (London) said that persistent chronic backache was inevitable if crush fractures of the lumbar spine were not reduced. Since the pain was due to mal-alignment of the spine, he doubted whether bone grafting would always relieve it.

Mr. **NAUGHTON DUNN** (Birmingham) advocated temporary splintage of the spine in order to decide whether bone grafting would be successful or not. Operative treatment could only succeed in those cases where pain was controlled by wearing a spinal support.

MEDICINE AND THE LAW.

A Doctor's Dog.

NOT long ago the House of Lords dealt with a claim for damages where a dog, left in an otherwise empty motor-car, had leapt at a window and, by breaking the glass, had caused a passer-by to lose the sight of his eye. In effect their Lordships decided that the owner of the car had not been at fault, there being nothing against the dog's previous good character. A somewhat similar claim has been made against a medical practitioner who left his car outside Queen's Buildings, Scovell-road, Borough, S.E., with his Sealyham terrier tied up inside in such a way that its muzzle could protrude only 3 inches beyond the car door. Two children came out of an adjoining house and leaned over the car to look at the dog; one of the children was bitten, and damages were claimed in respect of her injuries. There was important evidence that children were in the habit of playing in the street at this place, that the doctor had warned them not to interfere with his car or tease his dog, and that the injured child had heard the warning. Even more important was the absence of any evidence that the dog was of a ferocious nature, either to the doctor's knowledge or at all. It was stated that the doctor had said "the dog might bite"; but this, as Mr. Justice Du Parcq observed, did not mean that the dog was ferocious; any dog may bite if interfered with, especially if guarding its master's property. At the trial of the action on April 15th the jury disagreed. Apart from the question of damages, if any, they were asked five questions. They were unable to agree in answering any of these except that they answered "No" to the question whether the child had been guilty of contributory negligence. The other unanswered questions were: (1) Was the dog of a ferocious disposition? (2) If yes, was the defendant aware of its ferocity? (3) Was the defendant negligent in leaving the dog tied up in the car? (4) If yes, was his negligence the cause of the child's injuries.

In these conditions defendant's counsel applied for judgment. He emphasised the absence of evidence of ferocity, and he contended that every car-owner is entitled to leave a dog to protect his car; if the dog is tied in such a way that it cannot bite passers-by but only persons who trespass by touching or entering the car, there is no breach of duty and no negligence. On the other side it was argued that the dog was a potentially dangerous thing placed on the highway where it was likely to be a temptation to children. The learned judge inclined to give some weight to this argument; a child, he said, might naturally be tempted to look more closely at a car with a dog in it than an adult would. "A dog cannot differentiate between a little girl, an inquisitive man, a thief, or a policeman who wants to make inquiries." It was possible that a jury might think the owner was therefore bound to take such precautions as to make an accident impossible. Consequently he could not give judgment for the defendant; the case must be treated as one in which the jury had failed to agree; in other words, the plaintiff is at liberty to bring the action over again.

Death Sentence on Youth of Eighteen.

During the last 40 years, said Sir John Anderso before the Committee on Capital Punishment, nobod under the age of 18 years has been executed i England. The Children and Young Persons Bil proposes to make this age-limit of 18 statutory Jacoby was 18 years and 11 months when executed One, of the conditional recommendations of th Committee was that no one should be executed unde the age of 21. Youth is, of course, one of the element specially regarded by the Home Office in advising th commutation of the death penalty. In a recen case before Mr. Justice Travers Humphreys a yout of 18 was found guilty of murdering a girl of 6. He body was found in a tin box; examination showe that she had been outraged and strangled with cord. The accused's history showed abnormalit He was sent to a reformatory school at the age of for five years, after attacking a child 2 years ol whom he had left in a brook with his head cut ope The accused's paternal grandfather and matern grandmother had been inmates of a mental hospita His father said the boy showed no sense of causin pain or of fear, and had once put a cat down a stree grid. Medical evidence, called on behalf of th defence, was to the effect that he was of the moro type, a rather higher-grade mental defective, subje to alternate periods of dullness and excitemen The witness who gave this evidence said that th crime must have been committed in a frenzy sadistic lust. The judge told the jury that this wa not a defence of insanity. The law, said the judg provided nothing on the point of insanity concernin uncontrollable impulses. While this summing-up wa strictly accurate, it may be remembered that th Atkin Committee on the Criminal Responsibilit of the Insane (reporting after the case of Ronald Tru recommended that the law should recognise irrespons bility on the ground of insanity where the act wa committed under an impulse which the prisoner wa by reason of mental disease, in substance deprive of any power to resist. The Committee added tha it might require fresh legislation to bring this princip into effect. No such legislation has, however, bee passed; nor does the Home Office appear to hav made much effort in this direction. In the recen case described above, Mr. Justice Humphreys state that he should report to the proper authorities, wh would take into account the question of the accused' age and of any abnormality in his mental equipmen

BRITISH HEALTH RESORTS.

THIRD REGIONAL CONFERENCE.

THE conference held last Saturday was the third of a series designed to bring together medical men and representatives of local interests to consider the medical values of the region. The avowed aims of the British Health Resorts Association which summoned it are briefly these; to formulate the medical case for the British health resorts in the prevention and cure of disease, to differentiate on a scientific basis the various regions and places, and to make this information known to the medical profession and the public. These aims were well achieved during the week-end when the municipal fathers of Weymouth, Poole, and Bournemouth afforded lavish opportunity for a study of the strip of coast from Hengistbury Head on the east to Portland Bill on the west. The headquarters of the Association were nominally at the Bath Hotel in Bournemouth, and the formal discussions took place at the Town Hall, but in point of fact the whole of the week-end was given up to a roving conference over this western section of the southern coastal region, in which the local health officers and practitioners played a leading part.

At the first of the two business sessions the tone was set by a remark contained in a letter from Lord Meston, chairman of the Association, who was detained at the League of Nations meeting: We have, he wrote, lived too long in an inferiority complex about our own health resorts. And Sir Thomas Oliver, who took the chair at this session, was well within the mark when he asserted that there are few islands with such an imposing coast-line and such attractive scenery as our own, the number and variety of the coastal resorts being unsurpassed in any country. This session was noteworthy for a remarkable analysis by Lieut.-Colonel W. Byam of the various reasons given to him by patients in refusing to stay in England when advised to do so. These reasons, in descending order of frequency, were: (1) Climate: (2) the English standard of cooking; (3) the unfashionableness of home resorts; (4) the need for a complete change of scene; (5) the lack of amusements; (6) the ban on gambling; (7) the greater cost at home; (8) the absence of facilities for a cure. Colonel Byam said he regarded the third excuse as really the most potent, for since it is the wives who decide where to go, a health resort must be fashionable. The fashionable crowd is, he added, a great attraction for the seekers after health. Others who took part in the discussion concentrated rather on item 8, being the absence of facilities for a cure. Dr. Fortescue Fox pointed out how far we are behind the continent in organising our resorts as centres of convalescence in the wider sense, for those commonly called convalescent constitute but a small group in comparison with those who are never really well or actually ill, but yet have a right to hope for complete recovery. It was this vast and increasing number of subnormal people, many of them doing the best work in the community, for whom the health resort should organise its facilities. Dr. Manson-Bahr raised the question of diet at the British health resort, which was the thing that bothered him. No one seemed to be capable of making liver soup for his patients. There was no one to supervise the diet in the case of (say) sprue, where treatment was almost entirely dietetic. His difficulty would be met if there was a local panel to whom he could apply for help and information. He and others were in sympathy with Colonel Byam's plea for a centre on this strip of coast where modern medical diagnosis and treatment could be carried out; a nucleus providing facilities to every practitioner in the district. For such a purpose London hospitals with their noise were becoming more and more impossible. Dr. R. A. Young called upon the local medical profession to tell him more of what in their experience were the indications for regional treatment, what patients they should send, and at what time of the year: for, he said, you have on this coast many varieties of climate within a small area, and what will suit residual catarrh will not be equally good for emphysema. On sending down a patient he would like to be able to say to him: You will get specialised treatment there for your cough, and there for your shortness of breath, and so forth. How happy he and his fellow-consultants would be to give an honoured place on their waiting-room tables to resorts willing to provide facts like these. Some of these difficulties were set at rest later by Dr. Watson Smith's assurance that the speakers had not realised what was already being done locally. Practitioners, he said, knew all about liver soup and even the Gerson diet—either could be provided like any other dietary at any time; and he added some definite information about the climatic qualities of places like Canford Cliffs and Swanage.

It is worthy of note that the conference definitely discarded any narrow or parochial policy. We have, said Dr. Alfred Cox from the chair at the afternoon session, to think regionally. There must be regional coöperation and no petty jealousies. Colonel Elliot, whose letter to the *Times* last September set the whole movement going, disclaimed any such policy. We are, he said, in no sense hostile to continental or other interests; we are willing to coöperate with the foreigner if he is willing to coöperate with us. And at the great banquet the deputy-mayor of Bournemouth, Alderman C. H. Cartwright, speaking for all the resorts represented, said they did not claim patronage on grounds of patriotism; they wanted the public to go to British resorts because they preferred them. This led some of the consultants present to put in a plea for the large number of patients who cannot afford the tariff of an expensive hotel. There is an impression, all too well founded, that they can get better value for their money at many continental resorts than they do in this country. This again may be no more than a question of collating and supplying information about the accommodation available for all classes of the community and for every length of purse.

Finally, the outcome of the afternoon session was the unanimous adoption of a resolution to form a local branch of the British Health Resorts Association for the southern region, western section, nominations being received of both medical and lay members from Christchurch, Bournemouth, Poole, Swanage, and Weymouth. The mayor of Bournemouth, Alderman P. M. Bright, J.P., consented to act as convener.

BOLINGBROKE HOSPITAL, WANDSWORTH COMMON.—The old portion of this hospital is reported to be "daily becoming worse"; the main kitchen, dining and sitting-rooms, and servants bedrooms are gloomy and dilapidated. Rebuilding will cost £70,000, towards which the King's Fund has promised £1000. To tide over some of the difficulties temporarily Sir James Carmichael, the chairman of the board, has undertaken to defray the entire cost of an extensive scheme of improvement. Last year there were 2373 new in-patients and 13,495 new out-patients. The total weekly costs of the in-patients was £3 0s. 9*d*. and the total cost of each occupied bed £158 9s. 9*d*.

LONDON VOLUNTARY HOSPITALS COMMITTEE.

A YEAR'S WORK.

This Committee [1] which was appointed by London voluntary hospitals for the purpose of consultation with the London County Council, as provided by Section 13 of the Local Government Act, 1929, has issued the following report for the year ending March 31st, 1932.

During the period under review the Committee have been in constant communication with the Central Public Health Committee of the London County Council. Important decisions have been arrived at.

Acting upon the suggestion of the Voluntary Hospitals Committee, it has been agreed between the two committees to conduct a survey of the medical, surgical, and ancillary services in the county. The standing committee of the metropolitan borough councils have expressed their willingness to coöperate by supplying information relating to services for which the borough councils are responsible. The survey, which is in progress, will show the number of institutions in each area, distinguishing between municipal and voluntary; the accommodation available for each class of case; the staffing of each institution; the area from which patients are drawn; the facilities for extension; the need for further developments and other useful details. The task is one of considerable magnitude, as the survey involves institutions comprising some 100,000 beds. It is, however, hoped that it will be completed in the course of the next two months. It will provide the first authoritative description of the medical, surgical, and ancillary services of the county. The need for coördinated information is obvious. Without it the best use cannot be made of the facilities provided by each system, overlapping cannot be avoided, and economical effective progress is impossible. Further, without such a survey it is impossible to give effect to Section 13 of the Local Government Act, 1929, which provides for consultation between the municipal authority and the voluntary hospitals within its area.

Discussions have taken place between the two committees concerning medical education. As a result the Public Health Committee decided to continue existing arrangements between individual teaching hospitals and municipal hospitals. The extension of these arrangements is now being considered by both committees, and it is hoped that some more thorough and satisfactory means may shortly be devised which will enable a teaching hospital to be linked to a municipal hospital if and when desired.

The voluntary hospitals have welcomed the decision of the Public Health Committee to appoint salaried short-term resident house physicians and house surgeons for service in municipal hospitals, being of opinion that these appointments will provide valuable post-graduate experience. The two committees have also discussed various proposals made by the County Council for increasing accommodation at certain municipal hospitals, and for the establishment of special units such as those for thyroid cases and plastic surgery.

Projected scales of salaries and wages in municipal institutions have also been the subject of consideration. Statements regarding these matters have from time to time been issued to the Committee's constituent hospitals.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

LOANS TO UNIVERSITY STUDENTS.

The education committee of the Edinburgh town council have announced a scheme of loans to University students. These loans would cover attendances at all the courses of the University as well as at the College of Art, Veterinary College, Agriculture College, College of Domestic Science, and the Training Colleges. Edinburgh is the first burgh to adopt the scheme, which is in force in seven Scottish counties, Dunbarton being the pioneer. Applicants must be fully qualified for admission to the institution and course they are to attend. They and their parents or guardians must be resident in the city of Edinburgh at least twelve months prior to the application. They must supply to the committee a certified statement or declaration as to their income or other financial circumstances. They must sign an obligation to repay to the committee, within the time specified, all sums advanced, and this obligation must be endorsed by a responsible person or responsible persons accepted by the committee as a guarantor or guarantors for the due repayment of such sums. Before making payment of any instalment, the education committee may require evidence that the student is making reasonable progress with his studies, and in the event of their not being so satisfied, or of the student being guilty of serious misconduct, or of the student being no longer in a position to require such assistance from the committee, they reserve the right to suspend or discontinue the payments. In the event of failure to complete the course, the total amount advanced shall become repayable immediately. Unless in exceptional circumstances, and with the approval of the committee, the student must not hold any other grant, allowance, or bursary. The amount of the loan shall be in the discretion of the committee. The maximum amount of the loan and the normal periods of repayments are specified, and the sums vary from £25 to £150.

At present, the local education authorities give allowances to suitable students, and in administration no doubt difficulties will arise between the free grant and the loan; but there should be a place for both. In the early days of the Carnegie Trust relief of fees, any student could apply and receive; but later the University Carnegie Trust laid down the strict condition that where the student had not performed the work of the class he had to refund at once the amount received. This had a very wholesome effect on the work of the classes. There is talk of establishing competitive examinations both for the public bursaries or allowances and for the new grants.

Incidentally, the University of Glasgow advertised some time ago that the number of medical students to be admitted for the next winter session would be strictly limited. No doubt this comes of two facts: first, that the University is not prepared to extend its teaching staff to meet the rising demand; and, second, that care must be taken not to overcrowd the medical profession in the same way as the teaching profession in Scotland has become overcrowded.

---

[1] The Committee consists of forty members with Lord Riddell as chairman and Dr. Geoffrey Evans as honorary secretary. The other medical members are: Mr. A. Lawrence Abel, Lady Barrett, Dr. Edmund Colbeck, Mr. Robert Davies-Colley, Prof. L. S. Dudgeon, Mr. Charles Gibbs, Mr. E. L. Pearce Gould, Dr. A. M. H. Gray, Dr. Philip Hamill, Sir Henry Jackson, M.P., Dr. J. M. H. MacLeod, Mr. M. S. Mayou, Mr. Robert Milne, Mr. D. Denham Pinnock, Dr. Arthur Porter, Dr. Harold Pritchard, Mr. D. W. Roy, Dr. E. Bellingham Smith, Mr. T. G. Stevens, and Dr. C. M. Wilson.

LOW SCOTTISH BIRTH-RATE.

The birth-rate for Scotland during the first quarter of this year was 19·0 per 1000 of the estimated population, being 1·1 above that for the previous quarter, but 1·0 less than the average for the corresponding quarter of the previous five years. It is the lowest birth-rate recorded in Scotland for any first quarter since 1919, and with that exception is the lowest first quarterly rate on record. The death-rate, 16·2 per 1000, is 4·0 more than in the previous quarter, but is 1·2 less than the average. The marriage-rate, 6·3, is 0·3 below that for the previous quarter, but 0·3 above the average. The infantile mortality-rate, 113 per 1000 births, is 37 above the rate for the previous quarter, but is one below the average.

THE EDINBURGH CHAIR OF PSYCHIATRY.

Dr. D. K. Henderson, physician-superintendent of the Glasgow Royal Mental Hospital, has been appointed physician-superintendent of the Royal Edinburgh Hospital for Mental Disorders, in succession to the late Prof. G. M. Robertson, and has also been appointed to the chair of psychiatry in the University of Edinburgh. Prof. Henderson graduated in medicine at Edinburgh in 1907, and had the advantage of studying under the late Sir Thomas Clouston. He worked with Prof. Adolf Meyer for six years at the Psychiatric Institute, New York, and later at the Phipps Psychiatric Clinic, Johns Hopkins Hospital, Baltimore. He also studied under Prof. Kraepelin and Prof. Alzheimer at Munich, and with the late Sir Frederick Mott in London. During the late war he attained the rank of major in the R.A.M.C. His present post he has occupied since 1921, and he has also been lecturer in psychiatry in the University of Glasgow. Last year he delivered the Morison lectures on social psychiatry before the Royal College of Physicians of Edinburgh.[1] His range of illustration and catholic outlook, as well as his balanced criticism, made a great impression.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

THE GERMAN SURGICAL CONGRESS.

THE congress of the German Surgical Association was held as usual in Berlin during the week after Easter, with Prof. Voelker (Halle) as president. The first official subject of discussion was the surgical aspects of the liver, introduced by Prof. Henschen (Basle). He pointed out that in hepatic disorders with jaundice it is hard to say whether a patient will be able to stand narcosis or the shock of an operation. The disorder, whether functional or organic, prevents the liver from taking its share in detoxication and elimination—a share which should be large if renal efficiency is for any reason reduced. Biliary peritonitis, it was stated, has a doubtful prognosis, the toxicity of the bile varying considerably. Patients with hepatic disorder are apt to project their pain into the region of the appendix so that it is often regarded as a sign of acute peritonitis. On the other hand, acute appendicitis associated with hepatic disorder is liable to lead to suppuration of the liver, or acute atrophy. Allergic affections of the liver simulate acute cholecystitis or cholelithiasis, yet have no anatomical basis. In those cases cholecystectomy is unsatisfactory and cholecystotomy should be performed instead, so as to relieve the liver and give it a chance to recover. Prof. Brugsch (Halle) said that the depth of jaundice is decisive for the success of an operation; if icterus is long continued, damage of the liver may be presupposed. With mechanical occlusion of the bile-duct surgical intervention must not be postponed unduly. To diminish the danger of an operation the glycogen content of the liver must be increased by a diet of carbohydrates and albumin. Transfusion of blood, and in hepatic coma of phosphate, is recommended, while the activity of the liver should be promoted with Decholin.

The second official subject was gangrene of the extremities, introduced by Prof. Ceelen (Bonn). For a patient to recover from commencing gangrene it is essential, he said, that the cells of the affected organ should be intact and should have an adequate blood-supply. Gangrene caused by embolism and gangrene due to syphilitic endarteritis are especially dangerous. The reason why gangrene is commoner in the legs than the arms is the erect posture and the longer time required for the blood to flow from the heart to the legs. Diabetic gangrene is caused by sclerosis of the media, by which the circulation of the blood is locally retarded and the elimination of toxic substances is made more difficult. Juvenile gangrene, according to Ceelen, is not due to primary thrombosis with secondary inflammation but to a condition similar to chronic septic rheumatism caused by streptococci. A special constitutional liability to rheumatism must be present if juvenile gangrene is to develop. The surgeon must ascertain very early the symptoms in order to remove the causes. Dr. Roepke (Wuppertal), discussing the various causes of gangrene, said that early diagnosis and prophylaxis was essential to avoid amputation. Periarterial sympathectomy has not been so successful as was hoped, but the discovery of circulatory hormones has provided a powerful remedy. Prof. Bier (Berlin) warned his hearers against raising a limb in which gangrene is beginning, since this procedure will make it still more bloodless. He recommended the injection of animal blood.

The third official subject concerned the natural curative power of the body in surgical diseases and was introduced by Prof. Heile (Wiesbaden). He mentioned injection and transfusion of blood, diet prescriptions, and artificial production of fever by injection of albumin. Prof. Kubanyi (Budapest) dealt especially with the transfusion of blood and said that it was essential to preserve the natural temperature of the blood by special apparatus. Prof. Bohler (Vienna) spoke on fractures of the vertebræ and described his method of raising the compressed vertebra under local anæsthesia. A film demonstrated that his patients were able to perform gymnastic exercises shortly after injury.

A NEW HORMONE.

At the meeting of the Berlin Medical Society on March 16th Prof. Hermann Zondek reported on experiments performed by him and his assistant, Dr. Bier, on patients suffering from manic-depressive insanity. They found that the blood of those patients contained less than the usual quantity of bromine, but became normal between the attacks. They claimed to have discovered in the pituitary gland a new hormone containing bromide, and to have succeeded in isolating it in a soluble form. The new hormone injected into dogs produced a decrease of motor power, fatigue, and apathy. During sleep the hormone is said to be discharged from the pituitary gland into the fluid of the medulla oblongata which is then found to contain an increased quantity of bromine. When the patient wakes this discharge ceases, and the hormone is stored in the pituitary.

[1] See THE LANCET, 1931, ii., 80.

THE AFTER-EFFECTS OF TONSILLECTOMY.

Dr. Wirth and Dr. Lachenit, of the Heidelberg University Clinic, describe in the *Münchener medizinische Wochenschrift* the result of an investigation of the health of patients after tonsillectomy. The criticism has been made that the patient is more liable to contract infections, and to develop chronic pharyngitis and hoarseness; 200 patients were approached, of whom 92 consented to be examined and six answered questions by letter. All the patients declared themselves to be satisfied with their state of health; some complained of coryza, but these were mostly found to be suffering from some pathological condition of the nose, such as deviation of the nasal septum. In some cases scarring of the palatine arch has caused difficulty in speaking, but all the patients stated that they did not regret having undergone the operation.

ORESTHIN.

Dr. Schmidt writing to the *Centralblatt für Gynakologie* Nr. 3/1932 reports on his experiences with oresthin, an ecbolic compound of which 1 g. is equal to 1 g. of thymophysin. He has used it in 200 births and in 80 cases of induced abortion. Four injections are made of 0·5 to 1·5 g. at first and 1·0 g. when the head has entered the pelvis. In no instance has an infant died during birth. The duration of the labour is said to be considerably shortened by the drug, which is also indicated when separation of the placenta is retarded. Oresthin does not increase the blood pressure, a fact important in eclampsia.

PANEL AND CONTRACT PRACTICE

TEMPORARY RESIDENTS.

Provision is made under the National Health Insurance Acts for medical attendance on patients who may be from home when they require treatment. If away for less than twenty-four hours and the need is urgent the case can be treated locally under the distribution scheme as an emergency, the doctor being paid according to the emergency scale of fees adopted by the insurance committee of the area. An insured person who is away from home for a period of under three months can demand treatment from any local insurance practitioner by presenting to him the medical card after filling it up in space D. The doctor who accepts this card, signs it, and forwards it at once to the clerk of his local insurance committee, who returns it to the patient at his temporary address, at the same time sending the doctor who has signed it an envelope, with the name and address of the patient, his serial number, the society to which he belongs, and other particulars on it. When treatment is finished the doctor puts in it a continuation record card giving particulars of the illness, visits, consultations, and treatment. This special envelope is forwarded by the local committee to the home committee and so reaches the patient's home doctor. In this way the local committee have a record of the number of "temporary residents" attended in the quarter. Each doctor is paid for his attendance according to the local distribution scheme for this particular committee, the scale varying in different areas, but most committees allow six units for each temporary-resident patient as against one unit for the ordinary insured person. In the scheme of this arrangement, extra units were allowed for these cases because it was thought they would only receive attention when in need of it through illness, whereas the home doctor is paid his unit whether the patient is ill or not. Some committees allow eight units, others only four, for these temporary-resident cases.

CONVALESCENT HOMES.

But the matter is not quite so simple as this. Many insured persons obtain restoration to health through the assistance of convalescent homes maintained by approved societies at several well-known seaside resorts. After protracted illness the home doctor may advise a change to the seaside, and the society on application will send the patient to one of their convalescent homes, when it is usual for the home doctor to give a special intermediate convalescent certificate, if incapacity has lasted 28 days. Such a certificate covers 14 days and it can be given on any weekday between one Sunday and the next. This arrangement really covers three weeks. Thus if the special certificate has been given (say) on Monday, April 4th, no further certificate is needed until the week beginning Monday, 18th, and the patient could return home on Saturday, 25th, and obtain the necessary certificate from his home doctor on that day without infringing any regulations. He would then have been away from home 21 days, without needing the services of any insurance doctor in the area in which he was temporarily residing. Practice is, however, often different from theory. A small convalescent home will be in charge of a matron, a large home will have a medical officer who may be honorary or may be paid by the approved society. In either case it has become the nearly universal practice to collect the medical cards of these insured persons on arrival at the home. These cards are then signed in part D by the doctor to the home, who thus is credited with the appropriate number of units for each temporary resident in the home. This happens whether the convalescent requires treatment or not. Special consideration has been given in most local distribution schemes to this matter and the usual allowance is one-quarter that of the ordinary allowance—i.e., 1, 1½, or 2 units according as the usual rate of 4, 6, or 8 units for a temporary resident.

ADJUSTMENT OF THE CENTRAL POOL.

The insurance committee derives approximately 9s. a year (less 10 per cent. at the present time—a point which seems to have escaped public attention when every other cut has been noticed) for each insured person living in its area—i.e., on its register—but this does not include payment to doctors for their treatment of persons who have come to stay temporarily in its area. The money for the payment comes out of the central practitioners' pool and has to be added to the committee funds for this purpose to cover the extra units. The amount is arrived at by the Ministry of Health according to the returns furnished by each committee of the number of insured persons for whom temporary-resident treatment has been provided, and from which insurance committee's area they have come. Every insurance committee will send some of its insured persons into other areas and will itself receive insured persons from other areas. Before the central pool is divided up, a temporary-resident adjustment is made, some committees by way of addition, others of deduction. The former are chiefly the seaside and health resorts; the latter the big commercial areas. In 1930 the distribution committee decided to advise the Ministry that all ordinary temprorary-resident cases should be credited at a case value of 8s., those in a convalescent home at 2s.; previously the amount paid by a home committee to the committee of temporary residence for the treatment of its cases varied from 20s. to 3s. 6d. The amount paid was that committee's "case value" as shown by the work done for temporary residents in its own area. This was found by adding up (at 2s. 6d. per item) all items on all the temporary-resident cards sent in and dividing by the number of cards. London was found to have a case value of about 12s., and as London sends away many more temporary residents than it receives, this meant that the London insurance committee had deducted from its share of the central pool a large number of 12s. The average of case values for all committees was found to be about 8s. Hence the advice tendered to the Ministry.

ADDITIONS AND DEDUCTIONS.

The figures given by the Ministry to the distribution committee are in percentages of the total number of insured persons. The comparison of these figures becomes easier if for each addition or subtraction the figure for 10,000 persons in each committee is given. Thus London has as apportionment of index register 12·9748 per cent. and a temporary-resident deduction of 0·714 per cent. The deduction therefore for 10,000 would be 55. The comparative figures worked out on this basis for 1930 and for 1931 are as follows for a few committees:—

DEDUCTIONS.

	1930.	1931.
London	54 ..	55
Birmingham ..	33 ..	31
Newcastle ..	18 ..	41
Manchester ..	33 ..	36
East Ham ..	21 ..	22
Hull..	10 ..	18
Liverpool ..	19 ..	19
Cardiff	34 ..	34
Swansea	18 ..	28

The average deduction for England is 20·8, for Wales is 5.

ADDITIONS.

	1930.	1931.
Southport ..	440 ..	447
Blackpool ..	593 ..	501
Hastings ..	384 ..	348
Sussex. West	158 ..	147
Yarmouth ..	373 ..	419
Lincoln (Lindsay)..	138 ..	158
Cornwall ..	89 ..	94
Isle of Wight	178 ..	176

The average addition for England is 18·4, for Wales is 60.

One committee (Bucks) has changed from an addition of 1·5 last year to a deduction of 18 this year; Walsall had a deduction last year and is +0 this year. The committees which have additional credits this year as against deductions last year are: Leicestershire, Bath, Canterbury, Carlisle, Exeter, Gloucester, Plymouth, and St. Helens.

OMISSION TO DISCLOSE.

A not uncommon source of irregularity in panel practice is the patient's omission to disclose at the outset that he is an insured person. A case of this kind in South-West London resulted recently in an adverse decision by the Minister of Health against the practitioner. The patient had left the district of his former panel doctor and was now in a house in London. The respondent practitioner was professionally visiting that house in order to attend the patient's wife and another person. On Jan. 5th, 1931, the practitioner was asked to attend the patient himself who omitted to say that he was an insured person. Two days later the wife, calling at the practitioner's surgery for some medicine for herself, handed in her husband's medical card to a nurse employed in the surgery. Next day, calling again at the surgery, the wife was given by the nurse a national insurance certificate on Form Med. 40 (revised) signed by the practitioner under date of Jan. 5th, certifying that the husband was incapable of work. The husband was suffering from rectal abscess and was dressed daily at his home by a dresser employed by the practitioner. After a fortnight's confinement to his house, the husband continued to attend at the surgery to be dressed, the practitioner supplying the dressings. Certificates on Form Med. 40 (revised) continued to be signed. At the end of January or beginning of February a clerk employed by the respondent practitioner stamped the patient's medical card with the respondent's signature and forwarded it to the insurance committee. On or about Feb. 10th the respondent received the patient's medical record card from the committee. The respondent's clerk sent the patient an account for fees amounting to £6 13s. 6d. in respect of attention between Jan. 5th and Feb. 9th (both dates inclusive). The patient communicated with the insurance committee and paid
the account. Later, after the committee
communicated with the respondent, the amoun
refunded to the patient. In August the co er

payment were a breach of the terms of ser
inquiry committee contented itself with
mending that an order be made against the responden
for costs. The Minister thereupon ordered him to pay £5 towards the insurance committee's costs but took no step to remove his name from the Medical List.

The practitioner appealed against the insurance committee's decision to censure him and to ask the Minister to withhold £50. The tribunal found the facts established as before and recommended dismissal of the appeal. The appellant said his dresser told him that the patient desired to be treated as a private patient. The tribunal observes that Article 10 (1) would prohibit compliance with such a request. The appellant said he discussed with his clerk whether he was entitled to charge the patient, and that the clerk said the patient was not on his list till Feb. 10th when the medical card was returned by the insurance committee. The tribunal say that such a view is unfounded and that the practitioner cannot shelter himself behind his clerk's ignorance. The result is that the Minister dismisses the appeal, formally censures the practitioner, and directs £50 to be withheld; he also directs that the appellant pay £5 towards the costs of the appeal.

One point in the proceedings is unusual. Under Article 33 of the Regulations the Medical Service Subcommittee may in its report draw attention to any previous reports made in connexion with the practitioner's history. The subcommittee included in its report a mention of three criminal charges against the practitioner of having performed illegal operations. In each of the three cases he had been acquitted after trial, and he naturally protested that the subcommittee had included matters in respect of which it had itself made no inquiry or report and matters relating to charges on which he had been acquitted. The inquiry committee seems to have upheld this protest and to have declared that the complainants were not justified in referring to these matters in their representation. "The fact that such charges had been made against him was clearly calculated to prejudice the consideration of his case, and, inasmuch as he had been held by a competent tribunal to be innocent of them, the fact that they *had been made was clearly irrelevant.*" This is a very proper comment. It seems a pity, indeed, that the Minister was unable to award costs against complainants who were guilty of such manifest unfairness.

PUBLIC HEALTH SERVICES

MENTAL HOSPITAL REPORTS.

IT is impossible to review the 119th annual report of the ROYAL EDINBURGH HOSPITAL, MORNINGSIDE, without reference to the tragic loss to that hospital and to psychiatry caused by the death of Dr. G. M. Robertson only a few weeks after he read the address here printed. As usual, his report is far more concerned with the general situation of the mentally sick and the possibilities of prevention than with any dry official statistics. During 1931 the admissions to the four houses numbered 538, and 326 out-patients attended the Jordanburn Hospital and the University Psychological Clinic for Children. Of this total of 864 less than 12 per cent. were certified, and the the ole of the work was done without cost to the rate- being rs. The new children's clinic has received adopted atients since its opening in February, 1931, treated about half that number. The An insured r s proved invaluable for observation period of under The cases seen at the out-patient from any local inoyal Infirmary were classified as to him the medical uroses and neuroses, 36 per cent.; The doctor who acnt.; bodily diseases with mental forwards it at once to ervous disease, toxæmia, endo- committee, who retur systemic diseases), 15·5 per blems in juveniles, 6 per cent.; temporary address, ant.; addictions (drugs, alcohol), doctor who has sign g House and the West House name and address of nts at the end of the year, 170 the society to which lcertified, and 137 patients were on it. When treatmet nursing homes which have been it a continuation recbs and country round Edinburgh. illness, visits, co came from all over the English- special envelope ; some came from England and scape certification and one came from to the home, be placed in "the best institution in home doc Over 150 students attended the course have a truction last year; the value to the future doctor att this very extensive and representative psychotherapeutic material is very great. In concluding his report, Dr. Robertson reviews the intervention of the sheriff and urges his replacement by some responsible body such as the Board of Control or the Department of Health.

The ABERDEEN ROYAL MENTAL HOSPITAL had 860 patients on its register on the last day of last year. Of the private admissions, 39·6 per cent. were voluntary and four rate-aided voluntary patients were also admitted. The recovery-rate for the year was 40 per cent. among the voluntary patients and 24·09 per cent. among all the patients together. The death-rate was 8·9 per cent. The dental surgeon continued his visits throughout the year and saw a large number of patients. The work in the occupational therapy department continues to give gratifying results, and many patients have benefited from the diathermy, high frequency and ultra-violet ray installation. During the year a tea-room and shop for patients and their friends was opened and is giving great satisfaction. The hospital is becoming overcrowded as the numbers steadily increase, but the directors have in view a plan of expansion. During 1931 a nursing-home for 20 patients was opened. It is pleasantly situated on Dee-side and is intended for persons threatened with or suffering from early nervous or mental disorders, such as anxieties, exhaustion, or depression.

The CITY OF LONDON MENTAL HOSPITAL, STONE, DARTFORD, had 658 patients on Dec. 31st last; the accommodation proved sufficient for statutory requirements but a number of private applications had to be refused. Of the 146 patients admitted during the year, 86 were either voluntary or temporary. The recovery-rate was 58 per cent. and the death-rate 6 *per cent. The general health* was good except for an epidemic of influenza and there was no dysentery or typhoid. Every ward now has a loud-speaker, and headphones are provided for patients in bed. An out-patient clinic has been established. Parole is granted on a liberal scale; 125 *patients are allowed* outside the estate and 213 are free within the grounds. During the year, one nurse and two attendants obtained their R.M.P.A. certificates.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 23RD, 1932.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 96 (last week 87); scarlet fever, 1632; diphtheria, 772; enteric fever, 18; acute pneumonia (primary or influenzal), 994; puerperal fever, 41; puerperal pyrexia, 113; cerebro-spinal fever, 66; acute poliomyelitis, 6; encephalitis lethargica, 10; *continued* fever, 1; dysentery, 18; ophthalmia neonatorum, 101. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the *London County Council on April 26th–27th was as* follows:—Small-pox, 128 under treatment, 3 under observation (last week 122 and 1 respectively); scarlet fever, 1487; diphtheria, 1327; enteric fever, 9; measles, 2655; whooping-cough, 424; puerperal fever, 16 (plus 7 babies); encephalitis lethargica, 225; poliomyelitis, 5; "other diseases," 96. At St. Margaret's Hospital there were 13 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was no death from small-pox, 3 (1) from enteric fever, 109 (48) from measles, 9 (1) from scarlet fever, 40 (5) from whooping-cough, 24 (6) from diphtheria, 33 (10) from diarrhœa and enteritis under two years, and 78 (11) from influenza. The figures in parentheses are those for London itself.

The fatal cases of typhoid and paratyphoid fevers outside London occurred at Oldham and Birmingham. Liverpool reported 12 deaths from measles, West Ham 7, Sheffield 6, Leeds and Derby each 4. Manchester and Birmingham *each reported 4 deaths from whooping-cough.* Diphtheria accounted for 6 deaths at Liverpool.

The number of stillbirths notified during the week was 319 (*corresponding to a rate* of 44 per 1000 births), including 71 in London.

CORRESPONDENCE

NOMENCLATURE OF DISEASES.

To the Editor of THE LANCET.

SIR,—It is open to doubt whether certain opinions expressed in your annotation on the sixth edition of "The Nomenclature of Diseases" will be endorsed by medical zoologists, and it seems well that, at the earliest opportunity, attention should be directed to the fact that in the section headed "Animal Parasites" (Appendix C) various errata have been allowed entry or have remained uncorrected from the fifth edition.

The most unfortunate of these, perhaps, is the rendering *Wauchereria* for *Wuchereria*. That this is not a mere incidental printer's error is evidenced by the fact that the misspelling is repeated throughout. Several other misprints of a similar character occur, but need not be specified. There are, however, certain dispositions to which zoological nomenclaturists may be expected to take exception. The names *Ascaris, Dracunculus, Dioctophyme,* and *Trichuris,* for instance, have been pilloried by Prof. Leiper, while *Hepaticola* has been held by Dr. Baylis to be synonymous with *Capillaria*. Attention may also be drawn to the heading "Phylum—Vermes." This is an incorrect juxtaposition which does not find a place in the previous edition, and has apparently been introduced as an emendation. There is, of course, no zoological phylum bearing the designation "Vermes," this being merely a term conveniently applied to a conglomeration of at least four separate and distinct zoological phyla. Such discrepancies cannot fail to be an additional source of concern to those in the unenviable position of having to reconcile common medical usage with the rules of zoological nomenclature, especially as the unwary may, not unnaturally, infer that the nomenclatural doubts and difficulties which have assailed medical zoologists for at least the past three decades have been happily resolved in this official publication. Such, unfortunately, is far from being the case.

As you, Sir, have seen fit to approve and advocate the retention of this appendix in "The Nomenclature of Diseases" you may, equally, be in a position to recommend that in future editions it may be found possible to correlate the decisions of the subcommittee with current zoological opinion and practice, though, under present circumstances at least, that may appear a matter of almost insuperable difficulty. On the other hand it should be borne in mind that such conventions as may affect the nomenclature of the causal agents of disease do not necessarily, if at all, apply to the nomenclature of the resultant diseases, and that changes in the former need not inevitably be followed by changes in the latter. In this matter the committee may be congratulated on a wise conservatism in retaining such names as "filariasis" even though no species of the zoological genus *Filaria*, in its present restricted acceptance, is known to cause disease in man.

I am, Sir, yours faithfully,

London, April 30th, 1932. WILLIAM NICOLL.

THE LATE SIR WATSON CHEYNE.

To the Editor of THE LANCET.

SIR,—In your issue of April 30th Sir Harold Stiles, in writing an appreciation of Sir Watson Cheyne, refers to him as "the last of the diehards to abandon antiseptics for a strictly aseptic technique," and later on Sir Harold Stiles writes that he thinks that ultimately Sir Watson became a convert.

Sir Watson was never a diehard. It is true that he was not carried away by every breath of theory, but he did most sincerely endeavour to incorporate in his work anything that was of value in newly introduced methods, and his adherence to the older methods of technique was not due to obstinacy, but to a definite, considered judgment that it was better. It is true that he used autoclaved dressings so as to obviate the weight of the older wet dressings, but these always contained a chemical antiseptic, and in other ways his technique altered very little. Nor was he the last of that school of thought, if such an obscure person as myself may claim to be considered. He and I often discussed this question, and he always deplored the teaching that chemical antiseptics do such an infinity of harm. He quite realised the excellent results that experts, working under good conditions, could obtain by the more modern technique; but he felt that, in less skilled hands, under less perfect conditions, the results would not be so satisfactory. When I was a registrar we worked out his statistics as to sepsis over a long term of years, and we found that it was only 0·7 per cent. of the cases which showed any sign of suppuration. Most of this sepsis seemed to have arisen after the patient had been returned to the ward. We expected that about every alternate house surgeon would have a septic case—i.e., about one case a year. Controversy dies sometimes from mere weariness, not because the protagonists of a theory have proved their point. Perhaps some day "local chemotherapy" will be reinvented.

I am, Sir, yours faithfully,

ARTHUR EDMUNDS.

Queen Anne-street, W., May 1st, 1932.

CŒLIAC DISEASE AND DWARFISM.

To the Editor of THE LANCET.

SIR,—In their paper on the Treatment of Megalocytic Hyperchromic Anæmia (THE LANCET, April 16th, p. 829), Dr. Janet Vaughan and Dr. Donald Hunter refer to a case of dwarfism in a girl of 16, particulars of which were originally published in an article on Megalocytic and Non-megalocytic Anæmia, by Dr. A. C. Hampson and myself (*Guy's Hospital Reports*, 1924, lxxiv., 193). I note that they think that the dwarfism was probably due to cœliac disease, and state that it was thought at the time to be a case of renal dwarfism. May I point out that the dwarfism had only been considered renal previous to our investigation? Unfortunately, we did not carry out the urinary or fæcal examination ourselves, but, in the absence of blood or appreciable albumin in the urine, we did not think that any weight should be attached to the report of "a few blood-casts" in the urine when apparently no other casts had been found. Against the classification of this case as one of cœliac disease must be considered the facts that at no time had she had any symptoms of the condition (which would have needed to be fairly severe to produce the degree of dwarfism that existed), and that the finding of "a slight excess of fatty acid crystals in the stools" was a purely microscopical finding, the stools being apparently not abnormal. In our opinion, the case was one of Addison's anæmia occurring in a child—a condition which was probably quite sufficient to account for the dwarfism, in common with almost any severe chronic disease occurring at this period of growth. I may mention that this child was admitted to hospital solely for operative correction of her severe genu valgum.—I am, Sir, yours faithfully,

J. W. SHACKLE.

Grosvenor-street, W., April 30th, 1932.

SPEECH AND INTELLIGENCE.

To the Editor of THE LANCET.

SIR,—I have been greatly interested in Dr. Morison's paper on Speech and Intelligence in your last issue. I note that lalling and baby-talk are regarded by him as synonymous. In an inquiry last year regarding the prevalence of speech defects in the elementary school-child in Coventry, lalling and baby-talk were differentiated. Lalling was regarded as an inability to produce the anterior-linguopalatal sounds l, t, d, and n, and baby-talk as the substitution of one consonant for another. Which is the correct usage? Lalling in this narrow sense was found to be an extremely uncommon defect and had no correlation with educational retardation. On the other hand 30 per cent. of the baby-talkers were said to be educationally retarded.

I am, Sir, yours faithfully,

May 2nd, 1932. M. J. MOIR.

REFERRED PAIN IN VISCERAL DISEASE.

To the Editor of THE LANCET.

SIR,—In your issue of April 30th Mr. David Ligat points out with justice that Mackenzie extended his original conception of the viscero-sensory reflex to embrace pain and hyperalgesia of all the layers of the abdominal wall supplied by sensory somatic nerves. But Mackenzie only used the term "viscero-sensory reflex," so far as the gastro-intestinal tract is concerned, to account for pain and hyperalgesia in the abdominal wall resulting from disease of the viscera. Mr. Ligat, on the other hand, applies the term "viscero-sensory reflex" to the reflex inhibition of intestinal movement which results from trauma applied to the sensory somatic nerves of the abdominal wall, and I must again insist that this reflex has nothing in common with the mechanism conceived by Mackenzie as the viscero-sensory reflex.

That stimulation of the somatic sensory nerves of the abdominal wall does cause reflex inhibition of intestinal movement through the agency of the splanchnic efferent nerves is no mere theory, but a fact as well established as anything in experimental physiology. But it cannot be argued from this that stimulation of the visceral afferent nerves in disease must cause a radiation of pain to the somatic nerves of the abdominal wall such as Mackenzie postulated.

I must confess to some scepticism as to "the phenomenon of visible peristalsis elicited by pinching up the skin and subcutaneous tissue of the abdominal wall in certain cases of intestinal obstruction." The visible peristalsis can be elicited so much more readily in these cases by intermittent deep palpation, or better still by getting the patient to take a warm drink. But let us assume for the sake of argument that my doubts are groundless, and that this reflex is as well established as Mr. Ligat would appear to believe. It is still nothing more than a motor reflex exciting intestinal movement, presumably through the agency of the parasympathetic nerve, and has no analogy with Mackenzie's viscero-sensory reflex theory. I am, Sir, yours faithfully,

Manchester, May 2nd, 1932. JOHN MORLEY.

PSYCHOLOGY AND MEDICINE.

To the Editor of THE LANCET.

SIR,—Dr. Crookshank's letter in your last issue is confirmatory evidence, if such evidence were needed, of the truth of my contention that the fundamental science is psychology, without prefix or suffix, and that the contributions of Freud and of Adler are to be seen in their true proportions *only in relation* to this general science. Judged in this way, Freud's contribution, both of fact and of explanatory theory, towers high above the other. But when one turns from psychology to philosophical first principles one finds that such facts and subsidiary hypotheses can be interpreted philosophically in more ways than one. Methodologically, the two points of view—the psychological and the philosophical—should be kept distinct, although, of course they are intimately related to one another.

The distinctive characteristics of Adler's views which Dr. Crookshank quotes are mainly of a philosophical nature and by no means peculiar to Adler. The purposive nature of mental activity, the fundamental unity of the individual, the freedom of the will—all these are parts of the teaching of many psychologists, myself included, independently of anything that Adler ever said or wrote. Such positions can be harmonised with much of Freud's teaching, even if Freud himself and some of his followers may not accept them.

In reading the works of some "individual psychologists," one gets the disquieting impression that they are "mixing their categories," and using a vague philosophical terminology to eke out a psychol , which is weak in empirical detail. As I said in my previous letter controversial points of a truly psychological (as distinct from a philosophical) nature can only be settled on the basis of prolonged and deep analysis of cases, and those who carry out analyses are likely to find no further need to under the banner of one man, or of one movement.

I am, Sir, yours faithfully,

Harley-street, W., May 2nd, 1932. WILLIAM BROWN.

ADVERTISING AND CANVASSING.

To the Editor of THE LANCET.

SIR,—The attention of the General Medical C has been called to a proposal to provide free attendance for purchasers of a commodity which to be sold through the agency of advertisement canvassers. I am directed to point out that registered medical practitioner who associated him with such a scheme might be held to have contravene the Council's Warning Notice in regard to ad and canvassing, and to have rendered himself liabl to be summoned to appear before the Council answer to a charge which, if proved, might serious consequences. The warning referred to as *follows* :—

> *Advertising and canvassing.*—"The practices by registered medical practitioner—
>
> "(*a*) of advertising, whether directly or indirectly, fc the purpose of obtaining patients or promoting his professional advantage; or, for any such purpose, procuring or sanctioning or acquiescing in the publicat of notices commending or directing attention to th practitioner's professional skill, knowledge, services, o qualifications, or depreciating those of others; or o being associated with or employed by those who or sanction such advertising or publication; and
>
> "(*b*) of canvassing or employing any agent or canvasse for the purpose of obtaining patients; or of sancti

or of being associated with or employed by those who sanction, such employment;

are in the opinion of the Council contrary to the public interest, and discreditable to the profession of medicine, and any registered medical practitioner who resorts to any such practice renders himself liable on proof of the facts to have his name erased from the Medical Register."

I am, Sir, yours faithfully,
NORMAN C. KING,
April 27th, 1932. Registrar, General Medical Council.

"VETERANS."

To the Editor of THE LANCET.

SIR,—With reference to the annotation under this heading in your issue of April 30th (p. 947), the following practitioners whose names appear in the Medical Register, 1932, have also been registered for 65 years or longer: Dr. Edmund Holland, of Hendon, registered on May 15th, 1863; Dr. Shephard Thomas Taylor, of Edgefield, Norfolk, on Oct. 21st, 1865; and Dr. C. G. H. Bäumler, now of Freiburg, on July 25th, 1867. Dr. Edmund Holland is the senior Fellow of the Royal College of Surgeons, and also the senior Member of the Royal College of Physicians. Dr. Michael Grabham, of Madeira, the present senior Fellow of the Royal College of Physicians, qualified in 1861, although he did not register until 1883.

I am, Sir, yours faithfully,
W. J. BISHOP,
Assistant Librarian, Royal College of Physicians of London.
April, 29th, 1932.

SCARLET FEVER AND STREPTOCOCCAL INFECTION.

To the Editor of THE LANCET.

SIR,—I was much interested in Dr. Whitfield's letter in your last issue (p. 955) as I quite agree that we ought to hesitate before accepting a streptococcus as the cause of scarlet fever. There is another point I would like to raise—namely, that of the value of scarlet fever streptococcal serum in the treatment of this disease. Are the results of treatment by scarlet fever serum in any way comparable with those obtained from the use of diphtheritic serum in the treatment of diphtheria? I have been unable to satisfy myself that the incidence of complications was lessened to any great extent in serum-treated cases, as opposed to non-serum-treated ones; moreover, the period of detention in hospital for such cases was no shorter than for those which had not been given serum.

I am, Sir, yours faithfully,
J. TODESCO.
Croydon Borough Hospital, May 3rd, 1932.

TOXIC EFFECTS OF PHENOLPHTHALEIN.

To the Editor of THE LANCET.

SIR,—Dr. Elizabeth Hunt's letter, informative and interesting as it is, would be of increased value if the dosage of phenolphthalein were indicated in the cases she describes. Wise and Abrahamovitch, writing in 1922, describe several cases in the U.S.A. showing "a peculiar polychrome eruption of the skin with bullous, vesicular eroded lesions of the genitals, and mucosæ." They stated that pigmented areas may persist for years and are liable to activity again on resumption of the drug, to which, it seems, according to every account, there is no establishment of tolerance. In 1923 further cases were observed and one in particular manifested nasal herpes. In general the dermatitis produced is stated to have closely resembled that caused by phenazone in susceptible people, and these seem to be usually persons with a seborrhœic skin (Wise and Parkhouse).

I have found no mention of pruritus with phenolphthalein exanthemata by other observers save Dr. Hunt, but I have known personally of two young neurotic female patients in whom the giving thrice daily of 7½ and 10 grains respectively of phenazone has produced a marked itchiness of the skin, but with no accompanying erythema.

I am, Sir, yours faithfully,
Queen Anne-street, W., May 3rd, 1932. G. AUBREY.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. I. S. Gabe is placed on the retd. list at his own request.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lt. J. A. Kerr to be Surg. Lt.-Comdr.

Proby. Surg. Sub-Lts. H. R. Vickers and B. R. Alderson to be Surg. Sub-Lt.

ROYAL ARMY MEDICAL CORPS.

Lt. G. R. M. Apsey relinquishes his temp. commn.

Lt. C. P. Allen (temp. commn.) to be Capt.

ARMY RESERVE OF OFFICERS.

Lt. J. Neil Leitch, from Reg. Army Res. of Off., to be Lt.

TERRITORIAL ARMY.

Lt.-Col. E. M. Cowell, from R.A.M.C., to be Col.

Lt.-Col. A. Ramsbottom, having attained the age limit, retires and retains his rank, with permission to wear the prescribed uniform.

INDIAN MEDICAL SERVICE.

Capts. R. N. Bhandari and A. J. C. Culhane to be Majs.

The prob. appts. of the undermentioned officers are confirmed:—To be Capt.: R. M. L. Still. To be Lts.: B. Temple-Raston (now Capt., prov.), Mazhar Hussain Shah, G. K. Graham, A. W. West, J. O'Neill, H. B. Macevoy, M. K. Bryce, M. M. Mansfield, J. Guthrie, J. L. O'Neill, and W. J. Stewart.

The undermentioned appts. are made:—To be Lts. (on prob.): G. R. M. Apsey and Hannes Hannesson.

A BIRMINGHAM HOSPITAL SHRINE.—A brick room at Dudley-road Hospital, Birmingham, has been transformed, at the cost of the staff and friends, into a shrine or chapel for the reception of patients who die in the hospital.

A DONCASTER INFIRMARY SWEEPSTAKE.—The Doncaster Infirmary Supporters (St. Leger) Association has been formed with the object of raising £50,000 by means of a sweepstake on the race for the St. Leger. The mayor of Doncaster was the first member to be enrolled, and the chairman of the committee is the honorary solicitor to the hospital. The annual subscription is 5*s.*; an office has been taken, and Miss A. E. Hanchett, the infirmary's appeals secretary, has been given six months' leave of absence to enable her to take the post of secretary of the Association. The hon. treasurer is the manager of a local bank. The proportions of the subscribed money to be allocated to the infirmary and to the members on the result of the race have not yet been determined. Membership forms are being sent to every house in the district served by the hospital and applications for membership have already been received from many parts of the country. The objects of the association appear to be wider than the organisation of a sweepstake, the rules giving powers "to take such steps by personal or written appeals, public meetings or otherwise as may from time to time be deemed expedient for the purpose of procuring contributions to the funds of the association, in the shape of donations, annual subscriptions, or otherwise" and "to subscribe to any local or other charities and to grant donations for any public purpose."

OBITUARY

SIR DAVID DRUMMOND, C.B.E., M.D.Dub., D.C.L., LL.D.

By the death of Sir David Drummond, in his eightieth year, Newcastle and the north of England has lost one of its most distinguished physicians.

SIR DAVID DRUMMOND.

[*Photograph by Lafayette.*

David Drummond, the third son of David Drummond, of Dunfillan, Rathgar, near Dublin, was born there in 1852. After completing his schooldays at Broadstairs and Rathmines, he received his early medical education at Trinity College, Dublin, and at the Meath Hospital, where he was a pupil of the great Stokes. He graduated M.B., M.Ch., at Trinity College in 1874, and, to extend his experience, proceeded to the medical schools at Vienna, Prague, and Strasbourg. In 1876 he took the higher degrees of M.A. and M.D. Dublin, and in the same year came to Newcastle and was appointed assistant physician to the Children's Hospital, where he succeeded a year later to the post of full physician. At the same time he was appointed physician to the Newcastle Dispensary, but resigned the latter post on being appointed honorary physician to the Royal Infirmary two years later.

Drummond's association with the Royal Infirmary was indeed intimate, for he served on the staff for the long period of 34 years, from May, 1878, to December, 1912, while concurrently, from July, 1879, to November, 1895, he held the post of pathologist to the institution. During the whole of that time he was an enthusiastic teacher; ever interested himself, he succeeded in stimulating others, and in keeping abreast of that rapid development of medical knowledge which took place during the period. At the University of Durham College of Medicine he was equally a great and abiding figure. He passed from one lectureship to another. In 1876 he was appointed lecturer in therapeutics, in 1878 in physiology, and in 1883 in pathology, continuing to teach that subject until he was appointed lecturer in medicine in 1905. He succeeded to the position of professor of medicine in June, 1911, and continued in that office until July, 1924, being emeritus professor at his death. He was President of the College from 1918 to 1924, and Vice-Chancellor of the University of Durham from 1920 to 1922. The abundance of academic and administrative duties which he discharged led to a keen interest in promoting good fellowship between members of the profession and in his taking practical steps for the advancement of medical education. He served for several years as secretary of the Northumberland and Durham Medical Society, and as editor of its transactions, and for a period was secretary of the north of England branch of the British Medical Association, of which he was President in 1921.

Drummond's earliest scientific bent was towards neurology, as is indicated by his writings on "Diseases of the Brain and Spinal Cord," "Paralysis from Peripheral Neuritis," "Anæsthesia in Functional and Organic Disease of the Nervous System," and other contributions of a similar nature. In later years he widened his scope, and became especially interested in specific aortitis and thoracic aneurysm, in the investigation of which he had a great and varied experience. In his presidential address before the B.M.A. in 1921 he expounded fully the text of his lifelong teaching by his plea for accuracy in clinical observation and its confirmation by the test of pathological findings, in order that clinical knowledge might be strengthened and that the statistics founded on death certification might correspond with fact. He was truly one of the great teachers of clinical medicine, and there are many men who will gladly acknowledge him as having been their master. As a consulting physician he enjoyed a deservedly extensive reputation, not only in the northern counties but throughout the country at large. A colleague writes of him thus: "His practical powers of observation enabled him to make rapid deductions, and to translate physical signs into terms of pathology, and he was at all times helpful alike to patient and practitioner. He was a most delightful colleague, always inspiring, never stale, and throughout his life a true and loyal friend. He was, moreover, a happy, genial companion, and enjoyed his leisure and his pastimes. In his younger days he was a keen cricketer, and had always been fond of country sport. Of wiry build and active temperament, even up to last autumn he could hold his own with much younger men on a long day's shooting."

Sir David Drummond was senior physician to the Northumberland War Hospital during the war, received the C.B.E. in 1920, and a knighthood in 1923. He retired from practice in 1926, in which year he was President of the Association of Physicians of Great Britain and Ireland, and was serving on the Royal Commission on Lunacy. He went to live at Beattock in Dumfriesshire, where his time was equally divided between *country pursuits*, which loved, and the study of literature, where his views were far ranging and controversial. Throughout his long successful life Lady Drummond was ever by his side. She was the daughter of a Newcastle man, Mr. George Angus, and they had six sons and four daughters. They lost one son in the war, and another son, that promising surgeon Mr. Hamilton Drummond who distinguished himself by service in the war was killed in 1925 as the result of a motor accident Lady Drummond and four sons survive him, one of whom is Dr. Horsley Drummond, a successor to his father as physician to the Newcastle Infirmary. The sympathy that goes out to Sir David's family will be accompanied by high appreciation of t usefulness of his life, of his fine professional example and of his contributions to the promotion of medi knowledge and education.

Prof. G. Grey Turner writes: "The death of Sir David Drummond removes a notable physician, who had occupied a leading place in Newcastle and the North of England for t greater part of a long life. He will always gratefully remembered by a very numerous su " of men, now scattered all over the world, who came under his influence, either as students or house physicians or young practitioners, and each will remember him for his sound teaching, genial personality, kindly influence, and timely help in one way and another. Drummond was a great clinician and clinical teacher, who constantly urged the importance of actual contact with patients. He was certainly best at the bedside or in the post-mortem room, for when the opportunity offered he was ardent to carry the lines of clinical examination into the domain of naked-eye pathology.

"When I first came under his influence as a student he acted in the dual capacity of honorary physician and pathologist in the old Royal Infirmary, and his keenness in both spheres was infectious. It certainly taught me the paramount importance of correlating the clinical findings with post-mortem examinations, and this was always uppermost in his mind and those who remember his presidential address at the annual meeting of the British Medical Association in Newcastle in 1921 will recollect that this was his theme. He was keenly interested in surgery—not as an art but as a therapeutic measure—and in those far away days he was often readier than some of his surgical colleagues to invoke its aid in doubtful cases. His long and intimate collaboration with his friend and colleague, Rutherford Morison, was very fertile and led to many notable enterprises. Their names will always be associated with the operative treatment of ascites in cirrhosis of the liver which, by-the-by, was an operation practised in Newcastle with much success until the day arrived when that particular type of disease seemed largely to disappear. It was always delightful to see Drummond at an operation on one of his own cases; no one was more enthusiastic, no one more anxious to understand the pathology. Later in my career I was accustomed to meet Sir David in consultation, and each case was an education for me. Though I always took great pains to elucidate beforehand every point that I thought might have a bearing on the condition, he was sure to pick out something I had overlooked, to which he always drew my attention in the kindest possible way, and only to my advantage. I shall ever be extremely grateful for his encouragement and often in the time of darkest failure. How much that meant to a young surgeon!

"On one occasion he gave a delightful address to the Students' Medical Society entitled The Detective in Medicine, and that certainly was a rôle in which he excelled. His own interest never seemed to flag and I well remember, when he was nearly 70, how he urged me to 'keep up your interest in medicine,' and for him that word was always used in its widest sense. His example of youthful enthusiasm carried on into old age was in itself a perpetual stimulus, which none could witness without being infected.

"An enormous consulting practice, together with his hospital work, and his duties in connexion with the medical school, often involved him in overwork and many anxieties, but he always had the saving grace of humour, and this often came to his aid and cheered up those about him even in grim circumstances. He was never tired of relating stories of his early medical life in Dublin, and it was then that the delightful Irish brogue, at other times imperceptible, became so apparent. It was only a few days ago that he made me join him in laughter concerning the adventures of himself and his old friend Watson Cheyne in a sailing expedition down the Rhine, when they were students together in Strasbourg, and now alas both are gone!

"In dealing with patients he was habitually courteous and kindly, but on occasion he could be—to say the least of it—unmistakably emphatic, and by observing his methods of handling difficult situations, young practitioners gained a great insight into the conduct of their work. All through the war, and in the excessively busy years immediately afterwards, his energy and capacity for labour were a constant example. It was quite remarkable how he would go off in the early morning to make a country consultation, and would carry on far into the night, apparently without fatigue. As a matter of fact it was only his spirit which carried him along for, though wiry, he was not really robust, and his temperament was of the nervous type. In spite of this he had fine courage, as was shown by the way he braced himself to face the ordeal of a much dreaded operation."

EVAN HERRING HARE, F.R.C.S. Eng.

Dr. Hare, of Hornsey, who died on April 25th, was born at Putney in 1851, and was educated at Guildford, Westminster, and St. John's College, Oxford, where he graduated as B.A. in 1872 and later as M.A. From the University he proceeded to St. Thomas's Hospital, and qualified as M.R.C.S. in 1876. In the same year he saw active practice in the war between Serbia and Turkey, as one of the surgeons sent out by Sir E. Letchmere's committee, and he obtained a considerable reputation by bravely completing a surgical operation when an attack by Bashi-Bazouks was momentarily anticipated. This incident, in which Mr. Fleming Sandwith was his companion, was described in our columns at the time (1876, ii., 624) and won him the Gold Medal for Valour from King Milan of Serbia. He also went to South Africa, as civil surgeon attached to the Army, in the Zulu War of 1879, but was prevented from rendering assistance to the troops by a severe fever which kept him in Natal until, on convalescence, he was invalided home. After a few years' practice at Kew he moved to Hornsey in 1886, and there passed the rest of his life, in active practice until 1920. In 1887 he became F.R.C.S. Eng., and in 1891 he produced an English translation of Dr. Theodor Puschmann's voluminous work, "Die Geschichte des medicinischen Unterrichts" (History of Medical Education). Unfortunately, after only a few copies had been issued, the whole of the rest of the edition was destroyed by a fire at the publisher's warehouse.

Dr. Hare married in 1885 Emily Lucy, daughter of R. N. Cummins. Four of their six children survive him, but his eldest and youngest sons were killed in the late war.

Sheffield Royal Hospital.—The South Yorkshire miners' welfare committee has promised to give £20,000 and, if necessary, £25,000 for the provision of a new X ray and massage department at Sheffield Royal Hospital. It is officially stated that the present department is not safe for those continually working in it.

Institute of Hospital Almoners.—The annual report records that during the last two years the number of women applying for training has much increased. The present economic situation has, however, checked the normal development of the work, and during the last few months not so many new almoners' departments have been established. In a preface to the report Lord Moynihan, president of the institute, expresses the hope that hospital boards will-not defer the establishment of an almoners' department on grounds of economy. "The prevention of waste," he adds, "is a part of the economy, and that, given a wide interpretation, is the business of the almoner."

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

DUTIES ON MEDICAL AND SURGICAL INSTRUMENTS.

THE House of Commons, on Wednesday, April 27th, considered the Budget resolutions on Report.

Mr. LAWSON moved an amendment to exempt from the duties chargeable under the Import Duties Act, 1932, any consignment of medical, surgical, or scientific instruments. He gathered from the Board of Trade Navigation Account that the total amount of medical, surgical, and scientific instruments imported into this country from abroad last year amounted in value to £337,000. The medical profession in this country were dependent for those instruments to that amount upon foreign countries. Any imposition of taxation upon the instruments imported from abroad would certainly increase the expenditure and the difficulties of the hospitals and of all who carried on work of that nature. There was another point. They knew that in scientific matters, and particularly in the higher branches of science, the more delicate the instruments were the less likely they were to be affected by boundaries. He believed that instruments of this kind were supposed to be more affected by an international outlook because of the great human needs for which they were designed, and therefore it was probable that doctors who needed operating and other scientific instruments would be solely dependent upon instruments which came from abroad.

The SPEAKER said that it seemed to him that a great many of these medical and surgical and scientific instruments were already liable to duty, and if that was the case those that were liable to duty would be exempted from the provisions of the Import Duties Act.

Mr. HORE-BELISHA said that the argument which had been developed by Mr. Lawson was one which appealed to the sympathy of the House and of the Government. If he had in mind any particular class of instruments in favour of whose exemption a powerful case could be made, that case could be presented to the Advisory Committee, who, under the existing law, would have power to recommend its insertion in the Free List.

Mr. H. WILLIAMS said that Section 1 (5) of the Safeguarding of Industries Act read as follows:—

> "For the purpose of preventing disputes arising as to whether any goods are or are not any goods chargeable with duty under this part of this Act, the Board may from time to time issue lists defining the articles which are to be taken as falling under any of the general descriptions set out in the said Schedule . . ."

Accordingly, if a new scientific instrument was nvented, all that the Board of Trade had to do was to add it to the list.

The amendment was negatived.

Mr. TINKER moved an amendment providing that if an article could not be sold at a reasonable price when produced in this country a duty should not be placed upon it when it came from abroad.

Mr. HORE-BELISHA replied that the Advisory Committee would have regard to reasonable price and would act as a safeguard to the consumer, and the amendment was negatived by 264 votes to 48.

HEALTH ADMINISTRATION IN INDIA.

On Friday, April 29th, the House of Commons went into Committee of Supply on the Civil Estimates. Captain BOURNE, Deputy-Chairman of Committees, was in the chair.

On a vote of £81,110 for the cost of the Department of His Majesty's Secretary for State for India in Council,

Sir SAMUEL HOARE (Secretary of State for India) said that he had always thought that perhaps the two greatest gifts that the West could give to the East were improvements in communications and improvements in health. He could report certain definit improvements in the province of health. Firs there was the advance that was being made in mastering the terrible scourge of leprosy. Leprosy surveys were being continued, and had already led to a great increase in the number of cases treated at small in clinics. These cases numbered over 24,000 the Central Provinces and 28,272 in Madras, a decade ago only about 8000 lepers were being for in the whole of India. A very interesting had also been made in the measures for dealing with another sourge of India—cholera. There was what was called a bacteriophage, which had been discovered It was a very minute parasite growing in the chol bacillus, and it could now be isolated for a pure culture. The varieties obtained had th power to destroy the bacilli of cholera very rapidly and they were added to the water-supply cholera had broken out or was likely to break out That had been done in the last 12 months in th Nawgong district of Assam. In this cholera season *and the last two cholera seasons, practically* cholera occurred in the area dealt with. If was confirmed by further observations, it constitute the most important advance which ever been attained in dealing with the most epidemic disease of India. A quite definite adva had also been made during the last 12 months wit the malaria survey for coping with another of th great scourges of the East.

After further debate, progress was reported.

PRISON ADMINISTRATION.

On a Vote of £394,110 for the salaries and of the Prison Commissioners and the Prisons England and Wales,

JUVENILE DELINQUENTS.

Dr. SALTER urged that juvenile delinquents should remanded to an observation centre where their re mental and physical condition could be ascertain instead of being sent to prison. The necessity, said, was now urgent, particularly having regard t the increasing number of juvenile delinquents to the very numerous cases, which were unfortunatel increasing in proportion to the whole, where ment and moral and physical damage had been caused *encephalitis lethargica*. He knew of two adolescen who were suffering from this disease and were sent t prison, whereas if they had been remanded to observation centre their condition would undoubtedl have been discovered. One of them actually died prison from the after-effects of the disease, obviously it was cruelly wrong that they should have been sent to prison. The other had paralysis the muscles of the eyeball and various other physi signs which would have led to instant detection altogether different treatment had the recommended by the Departmental Committee carried out. He could also give the Home Secreta particulars of the case of a young man who suffering from juvenile general paralysis of insane. He was in prison some months before it wa discovered what was the nature of the complain from which he was suffering, and he was removed an asylum. We were behind a great many othe countries in this respect. Belgium had admira observation schools for the purpose, and a caref graded system enabled the specialists who contr the institutions to decide what particular afte treatment was required. All kinds of inge physical and psychological tests were employed, an as a result the whole attitude of the authorit towards juvenile offenders had been modified. At t London County Council last week there was a longed debate on this subject, and he understood that general dissatisfaction was expressed by speaker representing all parties at the condition of things It was agreed on all sides that development in th direction he had indicated should be carried out. It was held, however, that it was not a matter for the County Council, but for the Home Secretary to decide the precise form under which the administration should be conducted. He hoped that Sir H. Samuel would give his personal attention to the matter.

PRISON DIETARY.

Referring to the question of prison dietary, Dr. Salter said that he supposed that the most important medical discovery of this generation had been that of vitamins. It was a discovery of equal importance to the discovery of antiseptics by Lister. It was known now how our mental faculties, our physical health, and our moral outlook could be modified, not merely by internal gland secretions, but by these vitamin substances that were taken in food. The supply of green stuff, green vegetables, particularly uncooked green vegetables, in prison was extraordinarily small and deficient. He spoke with some experience of this matter because he had been in prison on more than one occasion. It might be said that these were luxuries to which no prisoner was entitled. He submitted, however, that in view of modern knowledge as to the detrimental results of the deprivation of these vitamins they ought to be supplied to every prisoner. He asked the Home Secretary to consult his medical advisers on this matter in the hope that prison dietary would be augmented or modified in this direction.

TEST BY PSYCHOLOGISTS.

Mr. Lovat-Fraser said that it was now the opinion that children who got into trouble ought to be carefully examined; that their characters ought to be tested by psychologists. Their past life and their environments should be investigated, and that only then should the magistrates deal with them. The same thing was necessary with adult prisoners. At present we treated abnormal people as if they were normal, and punished them for their abnormality. We forgot that many of the inmates of prisons were mental cases, and that they were suffering from a mental disability which required sympathetic treatment and consideration. Was it right, for instance, to send to prison a neurasthenic whose case called for careful treatment and a cheerful and inspiring environment? The governors of our prisons ought to be medical and psychological experts, able to differentiate between different types of prisoners. The delinquent ought to be placed under a medical expert and only when all the circumstances of his case had been ascertained should a decision be come to as to his fate.

Mr. W. Hutchison said that he recently visited Maidstone Gaol, and asked the medical attendant some questions about the prisoners' diet. The medical attendant informed him that it was a scientific diet and that it had been discovered that prisoners for a short time after entering prison lost weight. Then they came to a point at which their weight went up, and they became much more healthy in the majority of cases than they had ever been before they came into prison.

Home Secretary's Reply.

Sir H. Samuel, replying to the debate, said that Dr. Salter had spoken of the necessity for observation homes, particularly for children and in London, and for special attention being given to the individual characteristics of the children and other delinquents so that medical or other measures might be adopted suitable to individual cases. That was, undoubtedly, of great importance, and Dr. Salter was entirely right in the view he had expressed. The present remand home in London was not satisfactory, but that was a matter requiring legislation. It concerned the County Council also, and if Dr. Salter could persuade the Council to take a forward view in the matter, no one would be more pleased than the Home Office or more ready to assist their efforts. The prison dietary had been framed after very careful medical investigation, and as a rule the prisoners put on weight considerably after they entered the gaols nowadays, but he would draw the attention of his expert advisers to the point raised by Dr. Salter, himself a medical man, with regard to the inclusion of fresh vegetables.

The debate was adjourned.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 27TH.

Control of Locusts.

Captain Peter Macdonald asked the Secretary for the Colonies to what extent, as a result of the recent recognition of the Imperial Institute of Entomology in London as the international centre for the collection of data on the movements of locust swarms, it had been found possible to expedite work in this connexion; and how many foreign governments were coöperating in the work at the present time.—Sir P. Cunliffe-Lister replied: The foreign Governments so far coöperating in the investigation into the breeding of locusts are those of France and Italy, covering their respective dependencies. The progress made already includes Anglo-French coöperation in an investigation of the breeding-grounds of the migratory locust in West Africa. His Majesty's Government have just received from the Committee on Locust Control of the Economic Advisory Council its fourth report, which deals with this question and is now under consideration. The programme of future work in coöperation is to be discussed at a further international meeting in Paris next July, and this will afford a convenient opportunity of considering any recommendations made in the report.

Silicosis.

Mr. Tinker asked the Home Secretary the number of workpeople in the coal-mining industry suffering from silicosis during the latest 12 months for which figures were available and the number who received compensation for this disease, giving separate figures for Lancashire.—Sir Herbert Samuel replied: Silicosis is not notifiable and the only figures I can give are those of cases under the Workmen's Compensation Act. The Returns under that Act show that in 1930—which is the last year for which figures are at present available—there were 20 cases in which coalminers recovered compensation for disablement from silicosis. Information as to the distribution of these cases is not complete, but so far as known, only one of them occurred in Lancashire. I may add that I am informed that the Medical Board, which was set up in June last, has not so far issued any certificate in respect of any coalminer in Lancashire.

Dangerous Drugs.

Mr. David Grenfell asked the Home Secretary what was the production in Britain during the 12 months ended Dec. 31st, 1931, of cocaine, codeine, dionin, heroin, morphine, and peronin; whether the production was in excess of the requirements for medical and scientific purposes; and whether the convention for the limitation of the manufacture of narcotic drugs was operative in Great Britain.—Sir Herbert Samuel replied: The answers to the second and third parts of the question are in the negative. The following statement deals with the first part of the question:

	oz.
Cocaine alkaloid and salts	14,903·036
Codeine	12,325·74
Dionin	2.013·06
Heroin (diacetylmorphine)	3,326·4
Morphine alkaloid and salts	46.520·74
Peronin	nil.

Offences against Young Persons.

Viscountess Astor asked the Home Secretary if, having regard to the increase in indecent assaults on young persons, especially on children under 12 years of age, the number of cases in which defendants are acquitted because the unsworn evidence of the child cannot be accepted without corroboration, and the difficulties of obtaining corroboration since these offences are usually committed when the child is alone, he will consider taking steps to give effect to the recommendations of the Committee on Sexual Offences against Young Persons that, whenever it is justifiable, the evidence of a child who appears able to tell a connected story will be taken on oath and that those conducting prosecutions should bear in mind that the absence of corroboration in the case of a child whose evidence has been given on oath is not a bar to a conviction.—Sir H. Samuel replied: It is obviously desirable that, wherever justifiable, the evidence of a child who can tell a connected story should be taken on oath and I am advised that in view of the judgment of the

Court of Criminal Appeal in R. v. Crocker (17 C.A.R. 4546) the absence of corroboration is not a bar in law to a conviction except where corroboration is required by Statute. The recommendations of the Committee on these points, which are really suggestions as to the presentation and reception of evidence were with other recommendations of the Committee commended to the careful consideration of all concerned in the circular which was issued from the Home Office on Sept. 17th, 1926. The recommendations in question were for the courts and others to consider rather than for the Home Secretary to give effect to; but no doubt the publicity given to the matter by this question and answer will attract the attention again of those concerned.

Mentally Defective Children.

Mr. RHYS DAVIES asked the President of the Board of Education whether the proportion of mentally deficient children to ordinary school-children was on the increase or decline in England and Wales.—Sir DONALD MACLEAN replied: During the last few years for which returns are available there has been practically no variation in the proportion of children in public elementary schools formally ascertained by school medical officers as mentally defective, but I am afraid that these figures cannot be used as a reliable guide to the actual incidence of this form of defect, owing to the absence of a strict uniformity of standard, and to other difficulties. The hon. Member will find a full discussion of the matter in paras. 86–90 of the report of the Joint Committee of the Board of Education and the Board of Control on the subject of Mental Deficiency, which was published in 1929.

Dangerous Drugs Convention.

Lieut.-Colonel FREMANTLE asked the Home Secretary whether British ratification of the 1931 convention for the limitation of the manufacture of narcotic drugs had yet been decided upon; and, if not, when a decision regarding ratification was likely to be made.—Sir HERBERT SAMUEL replied: It is the intention of His Majesty's Government to ratify this convention and, to enable this to be done, the Dangerous Drugs Act, 1932, was passed with the object of bringing our law into conformity with the provisions of the convention.

Lieut.-Colonel FREMANTLE: As this has already passed the other House how long will it be before there is ratification. Will it be before the summer?

Sir H. SAMUEL: I cannot give a precise date. We are in communication with the Dominions and Colonies on the subject.

MONDAY, MAY 2ND.

Opium Manufacture in India.

Mr. DAVID GRENFELL asked the Secretary for India if he could give figures showing the quantity and value of the opium manufactured in 1930–31 at the Government of India's opium factory; what part of this output was intended for consumption in India; and the total revenue of the Government of India from the sale of opium for consumption in India.—Sir S. HOARE replied: During the year ending Sept. 30th, 1930 (the latest date for which figures are available) 1,276,016 lb. of opium were manufactured, valued at Rs. 115,45 lakhs. Of this 705,067 lb., valued at Rs. 64·81 lakhs, were intended for consumption in India. The actual consumption was, however, much less. The Government of India sell opium for consumption in India to local governments at cost price. The excise revenue of local governments and administrations for the year ending March 31st, 1931, from opium was Rs. 318,72 lakhs, from which must be deducted charges, including the cost of the opium.

Mr. RHYS DAVIES asked the Secretary for India whether any steps were being taken by the Government of India to reduce the sale of opium manufactured at the Government of India's factory at Ghazipur for consumption in India, and what progress had been made in limiting the number of shops in India from which this opium could be purchased.—Sir S. HOARE replied: The distribution and sale of opium in the Provinces of British India is under the control of ministers responsible to their respective councils. The amount of opium manufactured at Ghazipur for consumption in India depends upon the demand from the Provinces. There has been a substantial and progressive reduction in recent years.

Question to Pensioners.

Mr. LOGAN asked the Minister of Pensions if he would authorise the deletion of Question 11 from Form M.P.I.F. 27; the present reasons for asking a man if he was in receipt of pension other than the disability pension and for particulars of all such pensions.

Mr. PRICE asked the Minister if he would delete Questions 12 to 18 inclusive from Form M.P.I.F. 27 in all cases where the pensioner was not in receipt of family allowances; whether his attention had been drawn to the objections pensioners had to the questions on the form; and if he would consult with the British Legion or some organisation representing pensioners, with a view to modifying the questions.—Major TRYON replied: The object of the form referred to is to secure the identification of pensioners. Inquiry for this purpose, which is made of a percentage of pensioners annually, was instituted to meet the express requirements of the Public Accounts Committee of this House to protect the Exchequer against personation. The answers to Questions 11 to 18 inclusive, in common with the answers to other questions on the form, serve a necessary purpose in this connexion, and I regret that I cannot agree to their omission.

Birth Control.

Mr. POTTER asked the Minister of Health if he would arrange for an early visit of inspection to the clinics for contraceptive advice in Withington and Crumpsall hospitals; and if he would make the report, when issued, available to Members of the House at an early date.—Mr. ERNEST BROWN replied: My right hon. friend will obtain a report on this work from the local authority and will then consider whether an inspection is desirable. He could not undertake to adopt the suggestion in the second part of the question.

Coroners' Juries.

Mr. EDWARD WILLIAMS asked the Home Secretary whether he would introduce legislation to provide that coroners' juries should in future be drawn from persons possessing such practical or theoretical knowledge as would enable them to weigh evidence properly before arriving at verdicts, and to provide for the preparation of lists of such qualified persons.—Mr. O. STANLEY (Under Secretary for Home Affairs) replied: No Sir. Legislation in the sense suggested would be incompatible with the jury system.

Animals and Poison Gas Experiments.

Lieut.-Colonel APPLIN asked the Financial Secretary to the War Office the number of horses and dogs, respectively, which had been the subject of poison gas experiments in Great Britain during 1930 and during 1931 at Porton, Cambridge, or elsewhere.—Mr. DUFF COOPER replied: Eight horses were used for experimental purposes at the Chemical Defence Experimental Station, Porton, in 1930. Apart from this, no horses or dogs have been used for experiments in connexion with chemical defence, either at Porton or Cambridge, during the two years in question.

TUESDAY, MAY 3RD.

Charter of the Radium Trust.

Sir ERNEST GRAHAM-LITTLE asked the Lord President of the Council whether any modification had been made of the terms of the charter of incorporation of the Radium Commission, by which it was required that one-half of the original members of the commission, to be selected by lot, should go out of office after a certain date and the remaining original members at a later date.—Mr. BALDWIN replied: The requirement in the charter of the National Radium Trust to which the hon. Member refers was varied by a supplemental charter granted to that body on July 23rd, 1931. I am sending the hon. Member a copy.

Birth Control Advice.

Mr. POTTER asked the Minister of Health whether clinics for contraceptive advice form an integral part of the maternity hospitals to which he distributed grants in aid.—Mr. ERNEST BROWN replied: No, Sir. Grants from the Exchequer are no longer paid direct to maternity hospitals, except for the training of midwives.

WOMEN'S NATIONAL HEALTH ASSOCIATION.—Our Dublin correspondent writes: "The Women's National Health Association held its annual meeting in the Royal College of Surgeons, Dublin, on April 28th, under the presidency of the Marchioness of Aberdeen and Temair. It is quite 25 years since Lady Aberdeen founded the Association. Its objects were, as she reminded the meeting, to arouse public interest in questions of health, to spread the knowledge of methods of preventing disease, and to promote the up-bringing of a healthy race. During the whole period of 25 years the Association has striven toward these ends, and the founder has a right to be proud of its achievements. Reports were read of the various activities of the Association—the Children's Fresh Air Fund, the Irish Goat Society, the Peamount Sanatorium, the Babies' Club, the Peamount After-Care Committee. Mr. H. E. F. Hall, superintendent of the Peamount Industrial Settlement, gave an interesting account of the progress of its work."

MEDICAL NEWS

University of Oxford.

The Romanes Lecture for 1932 will be delivered by Lord Moynihan, at 12 noon on Wednesday, June 1st, in the Sheldonian Theatre. Subject: The Advance of Medicine.

The examination for the degree of *Bachelor of Medicine* commences on June 15th and names of candidates must be received before May 31st. The examination for the degree of *Master of Surgery* commences on June 23rd and names must be received before June 4th.

University of Cambridge.

On April 30th the following degrees were conferred:—

M.Chir.—Hermon Taylor.

M.B. & B.Chir.—John Morris, Alan Eckford, A. G. J. Harris, and R. W. Malim.

M.B.—J. M. Matthew.

B.Chir.—R. M. Dowdeswell (by proxy), J. W. S. H. Lindahl, J. S. Barker, and A. H. Lankester.

Royal College of Physicians of London.

At a quarterly meeting held on April 28th, with Lord Dawson, the President, in the chair, the following members were elected to the Fellowship:—

Overseas.—Alexander Gordon Biggam, M.D. Edin. (Cairo); William Boyd, M.D. Edin. (Winnipeg); Roy Samuel Dobbin, M.D. Dublin (Cairo); Goldwin William Howland, M.B. Toronto (Toronto); Abd-el-Aziz Ismail (Cairo); Thomas William James Johnson, M.D. New Zeal. (New Zealand); Frederick Donald Herbert Blois Lawton, O.B.E., M.B. Melb. (Melbourne); Harold Douglas Singer, M.D. Lond. (Chicago); Hugh Stott, M.D. Lond. (Lucknow); and George Charles Willcocks, M.B. Sydney (Sydney).

Scotland, Wales, and Provinces.—George Allison Allan, M.D. Glasg. (Glasgow); John Alexander Murray Bligh, M.D. Liverp. (Liverpool); William Tregonwell Collier, M.C., M.D. Oxf. (Oxford); George Secretan Haynes, M.D. Camb. (Cambridge); Cyril Gray Imrie, M.D. Ontario (Sheffield); George Johnson Langley, M.D. Lond. (Manchester); William McAdam, M.D. Glasg. (Leeds); Percival Brooke Mumford, M.D. Manch. (Manchester); Alfred Parkin, M.D. Durh. (Newcastle-on-Tyne); and James Maclure Smellie, M.D. Edin. (Birmingham).

London.—Edward Arnold Carmichael, M.B. Edin.; Edward Holliott Creed, M.D. Oxf.; Daniel Thomas Davies, M.D. Wales; Stanley Dodd, M.B. Camb.; Geoffrey Hadfield, M.D. Lond., Charles Felix Harris, M.D. Lond.; Godfrey Taunton Hebert, M.D. Oxf.; Richard Anderson Hickling, M.D. Camb.; Robert Daniel Lawrence, M.D. Aberd.; Douglas McAlpine, M.D. Glasg.; Sir Frederick Norton Kay Menzies, M.D. Edin.; Charles Edward Newman, M.D. Camb.; Charles Cyril Okell, M.B. Camb.; William Gifford Wyllie, M.D. Edin.; and Frederick Hugh Young, M.D. Camb.

The following candidates were admitted members of the College:—

John Fleming Brock, M.B. Oxf., L.R.C.P.; William Donald Wykeham Brooks, M.B. Oxf., L.R.C.P.; Walter Ford Connell, M.D. Q.U. Ont.; David McKee Dickson, M.B. New Zeal.; Reginald Ellis, M.D. Manch.; Thomas Miles Gilbert, M.B. Melb.; Ronald Thomson Grant, M.D. Glasg.; Michael Kremer, M.B. Lond., L.R.C.P.; Reginald William Luxton, M.B. Manch.; William Henry McMenemey, M.B. Oxf., L.R.C.P.; Harold Eric Martin, M.D. Manch.; Roy Lee Midgley, M.D. Lond., L.R.C.P.; Vincent Philip Norman, M.D. Durh.; John Noel O'Reilly, M.B. Oxf., L.R.C.P.; Lucy Parker, M.D. Lond., L.R.C.P.; Roy Kemball Price, M.B. Lond., L.R.C.P.; Ahmed Fahmy Ragab, M.B. Cairo; Robert Dickson Roach, M.D. McGill; Terence Stanley Rodgers, M.B. Lond., L.R.C.P.; Thomas Newton Rudd, M.B. Lond., L.R.C.P.; Hassan Shukry, M.B. Cairo; Mohan Singh, M.B. Punjab; Agneswara Aiyer Sreenivasan, L.R.C.P.; George Macdonald Thomson, M.B. Sydney; Emrys Williams, M.D. Lond., L.R.C.P.; and Francis Seaton Winton, L.R.C.P.

The thanks of the College were given to Dr. Raymond Crawfurd for his services as Visitor to the Medical Faculty of the Egyptian University and for his report.

The following were appointed as College representatives: Dr. F. G. Chandler, at the forthcoming Centenary Celebrations of the British Medical Association; Dr. J. W. Carr, on the Professional Classes Aid Council; Dr. A. S. MacNalty, at the Eighteenth Annual Conference of the National Association for the Prevention of Tuberculosis; and Lieut.-Colonel F. E. Fremantle, at the Forty-third Congress and Exhibition of the Royal Sanitary Institute.

Licences to practise were conferred upon 137 candidates (113 men and 14 women) who have passed the final examination of the Conjoint Board and have complied with the by-laws of the College.

The following are the names and medical schools of the successful candidates:—

A. L. Abeyewardene, L.M.S. Ceylon, Univ. College; H. Agar, M.B. Leeds; S. D. Ahuja, M.B. Punjab, Charing Cross; S. T. Anning, Camb. and Leeds; C. G. Baker, L.D.S., Guy's; W. C. Barber, Camb. and Manchester; Sarah N. S. Barker, M.B. Leeds; C. G. Barnes, St. Mary's; G. P. Barua, M.B. Calcutta, London; A. S. Baxi, M.B. Punjab, London; F. H. E. Beckett, Guy's; Mavis W. M. Beddall, Univ. College; J. G. Billington, Camb. and St. Thomas's; M. Blashka, Charing Cross; Jane Bonnell, Wales and King's College; H. W. L. Broadbent, Camb. and St. Mary's; M. J. Brookes, London; G. H. Brookman, St. Bart.'s; J. D. Burrows, St. Thomas's; Lilian M. Buxton, Birmingham; T. A. R. Callender, London; J. Cann, Camb. and St. Thomas's; D. B. Cater, Camb. and Charing Cross; I. A. Cathie, Guy's; J. R. Chambers, Camb. and Middlesex; G. H. Cooray, Ceylon and Univ. College; F. N. Corfe, L.D.S. Guy's; D. R. Crabb, St. Bart.'s; G. W. Crimmin, Camb. and St. Thomas's; Elizabeth Curphey, Westminster; R. P. Dalal, M.B. Bomb., Bombay; P. H. Daly, St. Mary's; A. M. Davies, Bristol; D. T. Davies, Birmingham; T. G. Davies, Birmingham; E. A. Devenish, Univ. College; D. C. De Wet, St. Thomas's; L. Dexter, St. Bart.'s; G. E. Dunkerley, Univ. College; H. Edwards, Cardiff and Guy's; R. T. Elven, Guy's; Q. F. Evans, St. Thomas's; W. B. Evans, Camb. and St. Bart.'s; W. G. Evans, Camb. and St. Mary's; A. L. Eyre-Brook, Bristol; K. Fawssett, St. Thomas's; H. F. M. Finzel, Bristol; J. H. Fisher, Camb. and London; J. F. P. Forster, Birmingham; A. E. Francis, St. Bart.'s; L. Freeman, St. Bart.'s; T. A. Gavin, Guy's; G. H. Gibbens, St. Thomas's; R. G. Gilbert, St. Bart.'s; K. J. Gilchrist, Guy's; A. F. Goode, Birmingham; A. J. Grace, Oxford and Guy's; D. C. Green, St. Thomas's; L. Greenfield, London; Catherine E. I. Greenshields, M.B. Liverp.; J. N. Groves, Camb. and St. Bart.'s; C. S. Hall-Smith, Camb. and St. Bart.'s; O. C. Hamilton-Jones, Liverpool; C. F. Hamilton-Turner, Oxford and St. George's; G. R. Hargreaves, Univ. College; Helen A. Hatrick, Univ. College; F. R. Hayward, Guy's; W. N. Hine, Middlesex; R. A. P. Hogbin, Guy's; A. Hollinrake, St. Bart.'s; M. D. C. Hosford, St. Bart.'s; B. Hynes, Middlesex; D. H. Irish, Guy's; J. M. Jackson, St. Bart.'s; W. B. Johnston, St. Mary's; T. B. Jones, Camb. and St. Thomas's; T. B. Jones, Westminster; B. L. Kapur, M.B. Punjab, London; R. Kempthorne, Oxford and Univ. College; A. L. Kenyon, Manchester; L. Kessel, Guy's; Florence E. Kingsley, Westminster; R. Knox, Oxford and St. Bart.'s; W. Kravchick, St. Bart.'s; A. W. D. Leishman, Oxford and St. Bart.'s; A. A. Lewis, Guy's; J. R. B. McBride, St. Bart.'s; M. N. Mahmood, M.B. Punjab, Middlesex; Halle Marsten, Charing Cross; J. R. M. Martin, St. Bart.'s; A. R. R. Mears, Camb. and St. Bart.'s; G. J. Meikle, Camb. and Middlesex; J. Metcalf, Camb. and London; J. A. W. Miller, Guy's; T. D. F. Money, Camb. and St. Thomas's; B. C. Murless, Camb. and St. Bart.'s; W. Mushin, London; Alice M. Naish, Camb. and Royal Free; D. R. Narang, M.B. Punjab, London; R. W. Nevin, Camb. and St. Thomas's; E. Palmer, Camb. and King's College; G. B. Palmer, L.D.S. Guy's; A. Papert, Witwatersrand and St. Bart.'s; J. Parkes, Camb. and St. Thomas's; R. Parkinson, London; C. S. Patel, M.B. Bomb.; O. R. L. L. Plunkett, St. George's; C. B. R. Pollock, Guy's; V. T. Powell, Cardiff; F. Radcliffe, Camb. and St. Bart.'s; K. S. Ranganathan, Madras and St. Bart.'s; H. M. Rashid, Birmingham; J. C. Read, L.D.S. Guy's; L. Redhouse, Witwatersrand and Middlesex; R. G. Reid, Guy's; J. P. Reidy, London; L. O. Roberts, St. Bart.'s; J. Rosenberg, Guy's; E. B. Rotherham, London; A. C. Rumsey, Camb. and London; Frances N. Salisbury, Bristol; O. E. L. Sampson, Bristol; R. S. Sandhu, M.B. Punjab; S. B. H. Saunders, Camb. and St. Bart.'s; O. A. Savage, St. Bart.'s; G. C. Sawyer, Guy's; M. H. P. Sayers, St. Thomas's; E. F. Scowen, St. Bart.'s; B. Shanovitch, London; S. M. Silverstone, Camb. and Guy's; H. M. Singer, King's College; S. F. Smith, St. Thomas's; J. R. Strong, St. Bart.'s; S. C. Suggit, Univ. College; S. K. K. Sze, Camb. and St. Thomas's; W. S. Tegner, Oxford and London; E. H. Thierry, Univ. College; C. W. Thomas, Camb. and St. Thomas's; G. L. Timms, St. Thomas's; J. B. L. Tombleson, St. Thomas's; O. S. Tubbs, Camb. and St. Bart.'s; D. Turner, Birmingham; J. T. Turner, Camb. and St. Thomas's; C. M. Vaillant, Oxford and Liverpool; J. M. Vaizey, Camb. and London; O. J. Vaughan-Jackson, Oxford and London; D. P. Viljoen, Witwatersrand and St. Bart.'s; Lilian B. M. Watch, Royal Free; C. J. Watson, Camb. and St. George's; Phyllis E. Watson, Camb. and Charing Cross; Celia Weinstein, Royal Free; H. D. White, Camb. and St. Bart.'s; E. W. Wilkins, Birmingham; R. A. Wilmshurst, St. Thomas's; A. J. K. Wilson, Birmingham; W. Wilson, Camb. and St. Bart.'s; and M. Zinober, Cape and Middlesex.

The undermentioned diplomas were conferred, jointly with the Royal College of Surgeons, upon the following candidates:—

Diploma in Tropical Medicine and Hygiene.—G. Ameratunga, R. M. Buchanan, Dorothy D. Chacko, Jane G. E. F. Cummins, G. C. H. Franklin, H. S. Gear, A. Hoff, C. G. Hoole, S. R. Iyengar, S. Petiyagoda, A. V. Pieris, G. W. Puvimanasingham, H. Richards, J. Rodger, B. N. Sharma, Mabel I. Silver, R. Sivasambandan, J. T. Smith, R. H. B. Snow, C. A. Stanley, R. T. Unruh, and J. E. Walcott.

Diploma in Gynæcology and Obstetrics.—D. P. de Villiers.

Royal Medical Benevolent Fund Guild.

A dance, organised by this Guild, is to be held on June 9th in the Great Hall of the British Medical Association, Tavistock-square, London, S.W. It will be the thirteenth of a series, and the committee is anxious that members of the medical profession and others interested in this fund should lend their support. Tickets (single 6s., double 11s.) may be had from Mrs. Oldershaw, 26, Upper Wimpole-street, W.1.

University of Glasgow.

On April 16th the degree of M.D., with high commendation, was conferred on Dr. George Brown. The names of other recipients of degrees appeared on p. 913 of our issue of *April 23rd.*

University of London Medical Graduates' Society.

The Earl of Athlone, Chancellor of the University of London, will be the guest of honour at the annual dinner of this society to be held at the Langham Hotel on May 11th. Tickets may be had from the hon. secretaries at 11, Chandos-street, W.1.

Institute of Psycho-Analysis

Mrs. Susan Isaacs, D.Sc., will give a course of lectures at the London Clinic of Psycho-Analysis, 36, Gloucester-place, W.1, on Fridays at 8.30 P.M., from May 6th to June 24th, on the Contributions of Psycho-Analysis to Anthropology. Opportunity for discussion will be given at the close of each lecture.

An Italian Medical Prize.

It is announced from Rome that Sir Aldo Castellani, director of tropical medicine and dermatology at the Ross Institute, and physician to the Italian Hospital, London, is among four recipients of the Mussolini prize of 50,000 lire *awarded for special* distinction during the past year.

Royal Institution

*The annual meeting of the members of the Royal Institu*tion of Great Britain was held on May 2nd. Lord Eustace Percy was elected president, Sir Robert Robertson treasurer, and Major C. E. S. Phillips secretary, for the coming year. Among the managers are Mr. Ernest Clarke, F.R.C.S., Sir James Crichton-Browne, M.D., Dr. K. R. Hay, and Sir Arthur Keith, M.D. Among the visitors are Prof. G. E. *Gask, F.R.C.S.,* and Dr. Russell Reynolds.

Medical Missionary Work in the Tropics.

A conference of medical students on this subject will be held at the London School of Hygiene and Tropical Medicine, Keppel-street, London, W.C.1, on May 10th, from 3.30 to 7 P.M.

The Annual Medical Missionary Breakfast of the Medical Prayer Union will be held on May 11th, at the Refectory, University College, Gower-street, W.C.1, at 8 A.M. An address will be given by Dr. C. C. Chesterman, of Yakusu, Congo Belge, W. Africa.

Those desiring to be present at either of these gatherings should communicate with Dr. Tom Jays, Livingstone College, Leyton, E.10.

Mount Vernon Hospital Anti-Cancer Education League.

An inaugural meeting of this League was held on April 27th at the Town *Hall,* Windsor, the mayor, Mr. F. L. Ellen, being in the chair, and Dr. A. D. Crofts, medical officer of health, was also present. Dr. Malcolm Donaldson, in an address [illegible] purpose of the League, said that [illegible] be compared to a gigantic jigsaw puzzle, in which, although pieces had already been put in position, the whole picture would not be clear until the last piece was put in its place. On this great problem were many groups of workers, some studying the cause of cancer, others the treatment, and others again the best methods of early diagnosis.

His chief concern that evening was to stress the importance of early diagnosis. He referred to statistical reports which showed that in early cases of cancer of the breast, 80 per cent. were cured. It had been estimated that less than 50 per cent. of patients suffering from cancer sought medical advice in time to have appropriate treatment, and many could only be alleviated by means of drugs. The reason for this state of affairs was that cancer in its early stages gave rise to no pain and, generally, very slight symptoms. He pointed out that it was impossible to teach the public the symptoms that might suggest the possibility of cancer, and, moreover, that such a course would be inadvisable as it would only lead to people thinking about the subject every time that they felt unwell. It was this fact that had led the authorities at the Mount Vernon Hospital to inaugurate this League, in order to persuade every man and woman over 40 years of age to go and be examined by their doctors twice a year, to see that there was no condition present which, if untreated, might lead to cancer. If people could be induced to follow this method it would rid them of fear of cancer to a great extent. It was hoped to form centres, such as was being formed at Windsor, in every town in England. His address was followed by a demonstration of Dr. R. G. Canti's *film.*

Biochemical Society.

This society will hold its next meeting in the department of biochemistry at Oxford, at 2.30 P.M., on Saturday, May 7th.

Extension of Stannington Children's Sanatorium.

The *Duchess* of Northumberland last week laid th foundation-stone of a new open-air school in the ground of this sanatorium, near Newcastle-on-Tyne. The numbe of beds has increased from 40 in 1904, to 310, all occupied. The sanatorium serves six counties.

Honorarium to a Medical Man.

The Legislature of Trinidad has voted £200 as a honorarium to Dr. J. L. Pawan, government bacteriologis to the Colony, who has proved that bats were the carrier responsible for a recent outbreak of rabies in the island The outbreak was described by Dr. E. Weston Hurst an Dr. Pawan in THE LANCET (1931, ii., 622).

A Middlesbrough Difficulty.

Middlesbrough Hospitals Committee is experiencin difficulty in filling the positions of assistant house surgeon an physician. Two applicants who were offered the pos replied that they had already accepted other appointment It is officially stated that "the financial inducements are ample" and it is suggested that the scarcity is partly due to public authorities engaging so many medical men.

Visit to Italian Health Resorts.

A party of medical men will leave this country next September for a fortnight's tour of spas and other resorts in the Italian Alps, on the Lakes, and on the Ligurian Riviera. The group will be in charge of an English-speaking Italian doctor and will be conveyed through Italy in a special train. Each doctor will have the option of taking his wife, son, or daughter, and at the conclusion of the tour members will be at liberty to visit other parts of Italy. Details *may be had from the British representative* of the Italian State Tourist Department (E.N.I.T.), Major W. Stormont, 16, Waterloo-place, Regent-street, London, S.W.1.

Manchester Royal Infirmary.

The annual report shows that last year there were 11,487 in-patients, an increase of 184, and 48,693 out-patients, a decrease of *2000.* In-patients cost £3 *8s. 2d. per* week, and stayed an average of 17 days, as against 17·64 days in 1930. At the Barnes Convalescent Hospital, Cheadle, 1220 patients were admitted; they stayed 34·58 days on the average and the annual cost per occupied bed was £89 14*s*. 10*d*. By increasing the nursing staff from 224 to 270 it has been possible to reduce working hours. A preliminary training school for nurses has been established.

National Hospital, Queen-square.

A post-graduate course on diseases of the nervous system will be held at this hospital from May 9th to July 1st. Clinical lectures and demonstrations will be given at 3.30 P.M. each weekday except Wednesday and Saturday; there will be teaching in the out-patient department at 2 P.M. each weekday except Saturday, and pathological lectures at noon on Fridays. Further, *a* course of ten lectures on the anatomy and physiology of the nervous system will be given at noon on Tuesdays and Thursdays if there are enough applicants and there will be ten clinical demonstrations, chiefly on methods of examination of the nervous system, at 5 P.M. on the same days. Particulars may be had from the secretary of the Medical School, National Hospital, Queen-square, London, W.C.1.

International Union against Tuberculosis.

The Italian Fascist National Federation against Tuberculosis has placed at the disposal of this Union two scholarships at the Benito Mussolini Institute *in* Rome. These competitive scholarships, each of the value *of* 6000 lire plus board and lodging, are intended to enable foreign medical practitioners to stay at the Institute for the purpose of following a course of studies during an academic year of eight months (Nov. 15th to July 15th). They will preferably be awarded to young physicians who are already familiar with tuberculosis problems. The *kind of* work undertaken will be subject to an agreement between the director of the Institute and the candidate. The scholarships will be awarded at the meeting of the executive committee of the International Union in September next. The names of candidates, accompanied by particulars of their age, qualifications, and professional experience must be forwarded to the secretariat of the Union not *later than* July 15th. No candidature will be taken into consideration unless it has been forwarded by a government or association belonging to the International Union, and applications from Great Britain and Northern Ireland should reach the secretary of the National Union against Tuberculosis (Tavistock House North, Tavistock-square, London, W.C.1) before July 10th.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, May 10th.—5 P.M., THERAPEUTICS AND PHARMACOLOGY. Election of Officers and Council. 8.30 P.M., PSYCHIATRY. Election of Officers and Council. Dr. Noel H. M. Burke: Some Aspects of Mental Deficiency. (Cinematograph Demonstration.)

WEDNESDAY.—5 P.M., SURGERY: SUBSECTION OF PROCTOLOGY. Election of Officers and Council. 5.15 P.M., SUBSECTION OF PROCTOLOGY: UROLOGY. Joint Discussions: Urinary Complications of Diseases of the Large Intestine. Openers: Mr. Hugh Lett and Mr. Cyril Nitch, Urology. Mr. J. P. Lockhart-Mummery and Mr. Lionel Norbury, Proctology. Followed by Dr. Cuthbert Dukes, Mr. Landray, Prof. G. Grey Turner, and others.

FRIDAY.—5.30 P.M. (Cases at 4.30 P.M.) CLINICAL. Election of Officers and Council.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.1.

MONDAY, May 9th.—8 P.M., Annual General Meeting. 9 P.M., Annual Oration, by Sir James Berry, on Fallen Idols. Conversazione.

PADDINGTON MEDICAL SOCIETY.

TUESDAY, May 10th.—9 P.M. (at the Great Western Royal Hotel, Paddington, W.2), Prof. J. Ernest Frazer: Some Skulls and Other Old Bones.

HARVEIAN SOCIETY OF LONDON.

THURSDAY, May 12th.—8.30 P.M. (at Paddington Town Hall), Dr. Geoffrey Holmes: Spa Treatment: With Special Reference to British Spas. (Illustrated by film.)

SOUTH-WEST LONDON MEDICAL SOCIETY. Bolingbroke Hospital, Bolingbroke-grove, Wandsworth Common, S.W.

WEDNESDAY, May 11th.—9 P.M., Dr. H. Yellowlees: The Lunatick, the Lover, and the Poet.

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY, 11, Chandos-street, Cavendish-square, W.

THURSDAY, May 12th.—8.30 P.M., Dr. C. L. C. Burns: Individual Psychology and Catholic Belief.

LECTURES. ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, May 9th to SATURDAY, May 14th.—LONDON LIGHT AND ELECTRICAL CLINIC, Ranelagh-road, S.W. Evening Course in Physical Medicine, Mondays and Wednesdays at 8.30 P.M. Lectures and demonstrations of cases.—MAUDSLEY HOSPITAL, Denmark-hill, S.E.5. Course in Psychological Medicine. Afternoons only.—CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C. All-day Clinical Course in Diseases of the Throat, Nose, and Ear.—ST. JOHN'S HOSPITAL, Leicester-square, W.C.2. Afternoon course in Dermatology. (The above Courses are open only to Members of the Fellowship.)

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith-road, W.6.

MONDAY, May 9th.—10 A.M. to 1 P.M., Gynæcological Ward, Surgical Wards. Genito-Urinary Operations, Skin Department. 2 to 4 P.M., Operations, Surgical Wards. Medical, Surgical, Gynæcological, and Eye Out-patients. 4.15 P.M. (Lecture), Dr. Grainger Stewart: Subarachnoid [illegible]

TUESDAY.—10 A.M. to 1 [illegible] Surgical Demonstration, Throat [illegible] Department. 2 to 4 P.M., [illegible], Surgical, and Throat Out-patients. 4.15 P.M. (Lecture), Mr. Hamblen Thomas: Treatment of Deafness.

WEDNESDAY.—10 A.M. to 1 P.M., Medical Wards, Children's Medical Out-patients. 2 to 4 P.M., Gynæcological Operations, Medical, Surgical, and Eye Out-patients. 4.45 P.M., Venereal Diseases Demonstration.

THURSDAY.—10 A.M. to 1 P.M., Neurological Out-patients Fracture Demonstration. 2 to 4 P.M., Operations, Medical, Surgical, Genito-Urinary, and Eye Out-patients. 4.15 P.M. (Lecture). Mr. Simmonds: Injuries and their Medico-Legal Aspect.

FRIDAY.—10 A.M. to 1 P.M., Medical Wards, Skin Out-patients, Dental Department. 12 noon, Medical Lecture. 2 to 4 P.M., Operations, Medical, Surgical, and Throat Out-patients.

SATURDAY.—9 A.M. to 1 P.M., Throat Operations, Medical and Surgical Wards, Surgical and Children's Medical Out-patients. The lectures at 4.15 P.M. on Mondays, Tuesdays, Thursdays, and Fridays are open to all medical practitioners without fee.

UNIVERSITY COLLEGE, Gower-street, W.C.

THURSDAY, May 12th, and following FRIDAY.—5.30 P.M., Prof. W. R. Hess (Zurich): The Autonomic Nervous System.

ST. PAUL'S HOSPITAL, Endell-street, W.C.

WEDNESDAY, May 11th.—Dr. Nathan Mutch's lecture has been postponed.

ST. MARK'S HOSPITAL, City-road, E.C.

THURSDAY, May 12th.—4.30 P.M., Mr. L. E. C. Norbury: Some Complications of Diverticula of the Colon.

ST. PETER'S HOSPITAL, Henrietta-street, Covent Garden, W.C.

WEDNESDAY, May 11th.—3 P.M., Mr. F. J. F. Barrington: Symptoms, Signs, and Diagnosis of Renal Tuberculosis.

NATIONAL CENTRE AND POST-GRADUATE SCHOOL OF RADIOTHERAPY, Riding House-street, W.

WEDNESDAY, May 11th.—4.30 P.M., Mr. M. Donaldson: Radiotherapy and Gynæcology.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

MONDAY, May 9th.—5 P.M., Dr. H. MacCormac: Treatment of Syphilis.

TUESDAY.—5 P.M., Dr. W. N. Goldsmith: The Nervous System in Relation to Skin Diseases.

THURSDAY.—5 P.M., Dr. J. M. H. MacLeod: Infections of the Skin with Yeast-like Organisms.

MANCHESTER ROYAL INFIRMARY.

TUESDAY, May 10th.—4.15 P.M., Dr. E. B. Leech: Asthma Cures.

UNIVERSITY OF BIRMINGHAM.

WEDNESDAY, May 11th.—4 P.M., Mr. C. J. Bond: Some Aspects of Human Biology. (Fourth of five William Withering memorial lectures.)

THURSDAY.—4 P.M., Prof. Seymour Barling: Operative Treatment of Toxic Goitre. (Ingleby lectures.)

WESTERN INFIRMARY, Glasgow.

WEDNESDAY, May 11th.—4.15 P.M., Dr. A. A. Charteris: Radium Therapy.

Appointments

HENDERSON, D. K., M.D., Ch.B. Edin., has been appointed Physician Superintendent Royal Edinburgh Hospital for Mental Disorders, and Professor of Psychiatry in the University of Edinburgh.

London County Council: BARLING, B., M.D., M.R.C.P. (St. Mary, Islington), FATTI, L., M.B., B.S., M.R.C.S., L.R.C.P. (Highgate), HOOPER, O., F.R.C.S. (St. Stephen's), PEAKE, H. L., F.R.C.S. (St. Olave's), RICHARDS, A. M., M.D. (Dulwich), ROANTREE, W. B., F.R.C.S. (St. Pancras), SHEPHERD, T. (Miss), M.D. (St. James's), SIMMONS, J. H. M.D. M.R.C.P. (St. Alfege's), WILKIE, D., F.R.C.S. (St. Charles'), YOUNG, B. A., M.D., M.R.C.P. (St. Peter's, Whitechapel), Senior Assistant Medical Officers; BAYLEY, A. W., M.B., B.S. (Mile End), BOLAND, C. R., M.D., F.R.C.S. (Hackney), FIELD, A. B. (Miss), M.R.C.S., L.R.C.P. (St. Mary, Islington), GABE, J., F.R.C.S. (St. Alfege's), GIBBS, E. G., M.D., F.R.C.S. (Bethnal Green), HOSEASON, A. S., M.B., B.S., M.R.C.S., M.R.C.P. (St. Giles'), LIBMAN, J., M.R.C.S. (Archway), LINFORD, H. (Miss), M.D. (North Eastern), RATAZZI, L. L., M.B., Ch.B. (St. John's), SELBOURNE, H. A. H., M.D. (Lewisham), Assistant Medical Officers; JOHNSTONE, J. G., M.B., Ch.B. (Princess Mary's Hosp. for Children), Medical Superintendent: NASH. H. K. G., M.R.C.S., L.R.C.P. (St. James'), House Physician,

Certifying Surgeons under the Factory and Workshop Acts: BARNES, W. A., M.B., B.Chir. Camb. (Woburn Sands); CLAYTON-JONES, E., L.M.S.S.A., M.R.C.S. (Cranbrook).

Births, Marriages, and Deaths

BIRTHS.

CARLING.—On May 1st, at Normandy, Alton, Hants, the wife of Dr. W. Russell Carling, of a son.

LANGMEAD.—On April 25th, at The Royal Chase, Tunbridge Wells, the wife of Dr. L. B. Langmead, of a daughter.

PUDDY.—On April 28th, at Point House, Litcham, Norfolk, the wife of E. Ivimy Puddy, M.B., B.S., of a daughter.

SAVIN.—On May 1st, 1932, at 174, Sutherland-avenue, W.9, to the wife of L. H. Savin, M.D., F.R.C.S.—a son.

MARRIAGES.

GROSS—CUNNINGTON.—On April 29th, at St. Anselm's, Davies-street, W., Capt. K. H. A. Gross, I.M.S., to Joan Cunnington, of Gosfield, Essex.

PARKES—MCQUEEN.—On April 27th, at Christ Church, Quinton, Birmingham, Percy Whitehouse Parkes, M.R.C.S., to Mary Isabel, eldest daughter of Dr. and Mrs. A. D. McQueen, Quinton, Birmingham.

DEATHS.

BOURNE.—On April 24th, at Dale View, Willingdon, Henry Bourne, M.B., B.S., late of Devonshire-place, Eastbourne, aged 53 years.

DRUMMOND.—On April 28th, at Saville-place, Newcastle-on-Tyne, David Drummond, Kt., C.B.E., M.A., M.D., D.C.L., LL.D., of Marchbank Wood, Beattock, Dumfriesshire, in his 80th year.

HARE.—On April 25th, Evan Herring Hare, M.A., F.R.C.S., of Hornsey.

LAW.—On April 26th, at Littleham, Exmouth, Alfred Roberts Law, M.D., aged 86.

RODEN.—On April 24th, at The Hollies, Droitwich, suddenly, Percy Austen Roden, M.D., J.P., in his 73rd year.

RODRIGUEZ.—On April 6th, 1932, at Port of Spain, Trinidad, B.W.I., Faustin Albert Rodriguez, M.B., C.M., late Medical Officer, Arima, Trinidad.

SCATLIFF.—On April 29th, Harold Harris Elborough Scatliff, M.A., M.R.C.S., L.R.C.P., of Marine Parade, Brighton, aged 56 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

THE HEALTH OF MERCHANT SEAMEN IN 1930.

By Fleet-Surgeon W. E. Home, O.B.E.

The annual return for 1930 of deaths on vessels registered in the United Kingdom[1] has been recently issued, much the same in form as last year, though it no longer hints that it provides something like a death-rate. It tabulates the deaths of all seamen in the mercantile marine, and the ages at death of British and foreign seamen. All we want now to provide a death-rate is a considered statement of the numbers habitually at risk, and we should soon get that, as the Interdepartmental Committee has been deliberating now for two years. The return tells us that a census of seamen is now taken every year, by numbers and ages, and the relevant figures for 1930 might well have been printed in this return; formerly the census was taken only every five years. By the kindness of the Board of Trade I was able to find the figures in a supplement to the *Board of Trade Journal* for July 30th, 1931. The "First Crews" of ships were this year (1930) 237,110, but by the census figures, taken on March 31st, the number of seamen employed that day on all British ships were 194,633: 80 per cent. of "First Crews"; 127,518 British seamen, 14,433 foreigners, and 53,682 Lascars.

For British and foreign seamen the ages at death are stated in the return, those from violence, separately, in Table VI.; those by disease, jointly, in Table VII. By ages these deaths are grouped as in the Registrar-General's decennial supplement on occupational mortality, so it would have been convenient if the ages had been similarly grouped in the census, thus giving opportunity for calculating readily death-rates year by year. But death-rates are unfamiliar to the Board of Trade, being really a concern of the Registrar-General, and thus of the Ministry of Health; and the ages in the census are inconveniently grouped. When trouble has been taken to prepare and print four columns of deaths, at ages 20–24, 25–34, 35–44, 45–54, why make that trouble less than half its value by not reporting in each case the numbers from amongst which these deaths arose? Had this been done comparison could have been made with the death-rates of the army or the navy, in neither of which are there any material number of persons above the age of 45. As those in the merchant marine of ages 35–44 and 45–54 are reported together, this comparison cannot be usefully made. The Board of Trade had not this difficulty in mind, but it is implicit in the choice of age-limits they have made. It would be of advantage, too, to print the deaths at the particular ages of British seamen only, or separately, to assist in a comparison with those of other British workers, but we have no figures by reference to which we can interpret the combined ages at death of British and foreign seamen as given.

Though the numbers of seamen are fewer in 1930, the deaths from disease were more (for British seamen 370 against 324), but from violence they were less (316 against 431), and there were 100 fewer lives lost in casualties to the ships. Taking the deaths and census figures, we get a death-rate for British seamen 5·38, for foreigners 6·45, and for Lascars 5·1, figures quite likely to be correct to the first decimal place, and really what more does one want to make an effective comparison possible from year to year? The death-rate in the navy in 1930 was 2·47, in the army the same, but the average age in the army is 23, in the navy 27, and among British merchant seamen 32, and the older the group the higher the death-rate expected. The most frequent causes of deaths of British seamen from violence were: falls overboard or on deck, 46; falls down hatchways, 30; drowned in dock, 40; suicide, 37; missing at sea, 33. Nothing is said in the return, or anywhere else apparently, about the measures taken to diminish these deaths of seamen, while it may be pointed out that three pages of the report of the Chief Inspector of Factories for 1930 were devoted to accidents at the docks and to the assiduous preventive measures taken in behalf of dock labourers.

Among the deaths from disease we find these figures: circulatory system, about 60; pneumonia, 43; respiratory tubercle, 33; malaria, 12; enteric, 9; and small-pox, 1. Who is there to see that British merchant seamen are vaccinated or inoculated as they should be, who will consider how they get pneumonia, or if they suffer from lead poisoning? These are really questions for the Ministry of Health, and will doubtless be handed over to it by the committee. The Home Office, when it had charge of the health in factories, developed a good medical department, but in its 70 years of dealing with the health of seamen the Board of Trade has not got itself even a rudimentary medical staff, but has contented itself with intervening between the seamen and the experts of the Ministry of Health who might save the seamen's health.

Death-rates in 1930

from	pneumonia were	British, 0·33 ..	Lascars, 0·53
	pulmonary tuberculosis were	„ 0·26 ..	„ 0·59

Lascars have by statute 72 cubic feet, British 120. Five Lascars occupy the same space on a deck as three British seamen; are we surprised that the Lascars are more susceptible to pneumonia and pulmonary tuberculosis?

BLOOD GROUPS.

A meeting of the Royal Anthropological Institute on April 22nd, with Prof. G. Elliot Smith in the chair, was devoted to a discussion on Blood Groups.

Prof. J. B. S. Haldane began by drawing attention to the relationship between the very old science of anthropology and the young science of genetics. Physical anthropologists had accumulated an enormous mass of material that served certain purposes, but a very critical attitude was necessary when those data were used to support speculations of racial origins. Interpretation had become much more exact since the rediscovery of Mendel's work, but progress had been slowest with man, and much uncritical material in human genetics had been published. The evidence for the existence of genes in man was limited to certain rather rare pathological conditions and to the subject under discussion. Genetics included the facts grouped under heredity and those grouped under segregation; genetic analysis was based on the fact that a parent handed unto his child not characters but self-perpetuating units in the nucleus of the cell—genes or Mendelian factors. The visible expression of a gene varied with circumstances; the gene was, as it were, a photographic plate that needed developing. For instance, there was a gene which made the fat of rabbits turn yellow if their food contained carotene; if the rabbit was fed on swedes, however, the fat remained white. If, therefore, an anthropological character was to yield results capable of genetical analysis it must: (1) be determined by a small number of genes; (2) be separating the population into groups which were not particularly rare; and it must not (3) be strongly affected by environment; or (4) be subject to natural or social selection. All these criteria were so far fulfilled only for the set of characters which determined the blood grouping.

The inheritance of these characters was quite simple; there were only two types of chromosome, and therefore an individual could have only two of these genes; in gametic mitosis only one could pass to the germ cell. The child of an AB parent could thus receive either A or B; the child of two O parents could receive neither; the child of an A could have either two A's or one A and one inactive gene (R), and the same applied to a child of B. It was an absolute rule that the child could not have in its corpuscles anything that was not in the blood of its parents. If an AB married an O the children must have either A or B; none of the children would resemble either father or mother. If one parent belonged to the AB group no child could belong to the O group.

Prof. Haldane then quoted certain data showing how these laws of inheritance had been proved on very large series, notably by Haselhorst. Exceptions of the order of about five in a thousand had been found, but were all explicable as due to illegitimacy. Only one inexplicable case was known: an AB mother had had an O child. In all Mendelian work, however, exceptions of the order of 1/2000 were apt to occur: possibly the mother had had three chromosomes instead of two, or a mutation process had occurred.

RACIAL DISTRIBUTION.

Blood groups would give a clue to racial origins—though a largely negative clue—for their distribution varied in different races, and was affected very slowly, if at all, by environment. Hungarian gypsies, for instance, showed 6 per cent. of AB and 39 per cent. of B, while Hungarian Magyars showed 12 per cent. of AB and 19 per cent. of B, and Indians 9 per cent. of AB and 41 per cent. of B. A map of the world showing the proportions of the B gene gave remarkable "contour" lines, suggesting that a wave of B had started in Central Asia, and spread thence in all directions; B was unknown in Australia and very rare in Esquimos and the aboriginals of North, Central, and South America. The only sample giving more than 30 per cent. of B was taken in the Punjab, but B was also common in the Ukraine. A similar map for A would be difficult to make, because A consisted of two classes (A and A^1) which could only be distinguished by a refined technique.

Other genes by which races could be classified were corpuscular agglutinogens which gave a reaction with rabbit sera: these were called M and N; everybody had M or N, but the proportions varied in different races. Another differentiating quality was the ability to taste bitterness in dry phenyl-thio-carbamide placed on the tongue; about two-thirds of people appreciated no taste. The evidence suggested that this ability was a simple Mendelian recessive, in which case it constituted another differentiating gene unlikely to be influenced by natural or social selection.

Dr. L. S. Penrose said that his tests of over 500 mental defectives had shown only 2·2 per cent. of group AB. The study of blood groups in this country was very much neglected; in Germany a large survey had been made by local practitioners, and in Holland a national survey at a central institution had suggested some correlation between B and dark hair.

Prof. H. H. Woollard said that the centre of Australia had yielded no B at all, but 60 per cent. of A. This suggested that the aboriginal had colonised Australia from one small canoe party. He was of opinion that the blood groups had first appeared, by gene mutation, in a common ancestor of the apes and man.

Prof. Ruggles Gates described his tests of Esquimos in the Canadian Arctic: they were chiefly O, like the Red Indians, but a group at the mouth of the Mackenzie river had shown a very high percentage of B. The absence of A and B from these races indicated early isolation. Probably B had occurred as a mutation very much later than A. In a recent paper, work on Tierra del Fuegans had been described: Twenty-two Onas, living on the mainland, had shown 20 examples of O; 30 out of 33 Yaghans—a small island community numbering only 73 in all—had been B; two Alakalufes had both been B. It was extraordinary to find B—a central Asian characteristic—in this area!

Dr. H. Brewer described two donors who had come to him to be tested for the blood transfusion service; they had been classed as group O and had served satisfactorily four and five times respectively. Then some suspicion had arisen; they had been retested and grouped as "B," subsequently giving satisfactory service in that category.

Prof. Lancelot Hogben said that B was very high—about 23 per cent. in 600 cases—among the Bantu, and also among the Senegalese, about 21 per cent., but the grouping of the Bushmen was roughly that of this country. This indicated a drift of B southward, with the Bantu migration, into a country previously showing little B.

Dr. Morant asked if there were any sex differences in the blood groups.—Mr. G. Powell asked if there was any difference between the higher and lower social classes.—Prof. C. G. Seligman asked if the high percentage of B were associated with Mongol characteristics.

The Chairman said that anthropologists did not yet know how to fit these tentative new facts into existing ideas of race. Information was pouring in at an amazing rate, and it would be rash to try to formulate any comprehensive interpretation at present.

Prof. Haldane, in reply, expressed his preference for the diffusion theory, rather than the idea of a parallel origin. There were no sex differences; some German figures seemed to show a difference between criminals and professors, but class differences had not been fully worked out. B was not associated with Mongol characteristics; probably there had been a big outburst of B from Central Asia after China was more or less settled.

THE DEFILEMENT OF PAINT.

To the Editor of The Lancet.

Sir,—In the springtime many amateur house-painters splash paint on their faces, arms, and hands. The usual paint solvents are paraffin, turpentine, and linseed oil. There are objections to all. Linseed oil, though bland, has to be kept in a bottle and when being used is too easily flowing and spilt. I have discovered that white vaseline mixed in a jar with a requisite quantity of linseed oil and well stirred to a thick creamy consistency is most useful for removing paint spots from the skin without any deleterious effect. The jar can be kept handy and the cream should be thick enough not to spill or run when the jar is inverted. It can be applied with a small clean rag or the finger tip.

I am, Sir, yours faithfully,

London, April 14th, 1932. F. W. W.

COATS, GOWNS, AND SMOCKS.

Improved patterns in white drill coats and gowns for doctors and dentists are now available. Messrs. E. and R. Garrould, Ltd., supply a smock overall with short sleeves, which can be used where a full-length operating gown is not required, and short coats can be had with stand-up or ordinary tailored collars. The dentist's coat has removable buttons down the side and a belt at the back only. The operating gown can be supplied not only in white drill but in sterilisable waterproof material.

Dr. W. Benton (M.O.H., East Ham) informs us *that the son of a medical practitioner of Vienna*, aged 15, who speaks good English, is desirous of visiting England during the vacation, July and August. Board-residence is offered at his home in Vienna suburb, in exchange for the same in or near London, to the son of medical man about the same age. Communications should be addressed in the first instance to Dr. Benton, at the Town Hall, East Ham, E.6.

NOTES, COMMENTS, AND ABSTRACTS

THE HEALTH OF MERCHANT SEAMEN IN 1930.

BY FLEET-SURGEON W. E. HOME, O.B.E.

THE annual return for 1930 of deaths on vessels registered in the United Kingdom[1] has been recently issued, much the same in form as last year, though it no longer hints that it provides something like a death-rate. It tabulates the deaths of all seamen in the mercantile marine, and the ages at death of British and foreign seamen. All we want now to provide a death-rate is a considered statement of the numbers habitually at risk, and we should soon get that, as the Interdepartmental Committee has been deliberating now for two years. The return tells us that a census of seamen is now taken every year, by numbers and ages, and the relevant figures for 1930 might well have been printed in this return; formerly the census was taken only every five years. By the kindness of the Board of Trade I was able to find the figures in a supplement to the *Board of Trade Journal* for July 30th, 1931. The "First Crews" of ships were this year (1930) 237,110, but by the census figures, taken on March 31st, the number of seamen employed that day on all British ships were 194,633: 80 per cent. of "First Crews"; 127,518 British seamen, 14,433 foreigners, and 53,682 Lascars.

For British and foreign seamen the ages at death are stated in the return, those from violence, separately, in Table VI.; those by disease, jointly, in Table VII. By ages these deaths are grouped as in the Registrar-General's decennial supplement on occupational mortality, so it would have been convenient if the ages had been similarly grouped in the census, thus giving opportunity for calculating readily death-rates year by year. But death-rates are unfamiliar to the Board of Trade, being really a concern of the Registrar-General, and thus of the Ministry of Health; and the ages in the census are inconveniently grouped. When trouble has been taken to prepare and print four columns of deaths, at ages 20–24, 25–34, 35–44, 45–54, why make that trouble less than half its value by not reporting in each case the numbers from amongst which these deaths arose? Had this been done comparison could have been made with the death-rates of the army or the navy, in neither of which are there any material number of persons above the age of 45. As those in the merchant marine of ages 35–44 and 45–54 are reported together, this comparison cannot be usefully made. The Board of Trade had not this difficulty in mind, but it is implicit in the choice of age-limits they have made. It would be of advantage, too, to print the deaths at the particular ages of British seamen only, or separately, to assist in a comparison with those of other British workers, but we have no figures by reference to which we can interpret the combined ages at death of British and foreign seamen as given.

This indicated a drift of B southward, with the Bantu migration, into a country previously showing little B.

Dr. MORANT asked if there were any sex differences in the blood groups.—Mr. G. POWELL asked if there was any difference between the higher and lower social classes.—Prof. C. G. SELIGMAN asked if the high percentage of B were associated with Mongol characteristics.

The CHAIRMAN said that anthropologists did not yet know how to fit these tentative new facts into existing ideas of race. Information was pouring in at an amazing rate, and it would be rash to try to formulate any comprehensive interpretation at present.

Prof. HALDANE, in reply, expressed his preference for the diffusion theory, rather than the idea of a parallel origin. There were no sex differences; some German figures seemed to show a difference between criminals and professors, but class differences had not been fully worked out. B was not associated with Mongol characteristics; probably there had been a big outburst of B from Central Asia after China was more or less settled.

THE DEFILEMENT OF PAINT.

To the Editor of THE LANCET.

SIR,—In the springtime many amateur house-painters splash paint on their faces, arms, and hands. The usual paint solvents are paraffin, turpentine, and linseed oil. There are objections to all. Linseed oil, though bland, has to be kept in a bottle and when being used is too easily flowing and spilt. I have discovered that white vaseline mixed in a jar with a requisite quantity of linseed oil and well stirred to a thick creamy consistency is most useful for removing paint spots from the skin without any deleterious effect. The jar can be kept handy and the cream should be thick enough not to spill or run when the jar is inverted. It can be applied with a small clean rag or the finger tip.

I am, Sir, yours faithfully,

London, April 14th, 1932. F. W. W.

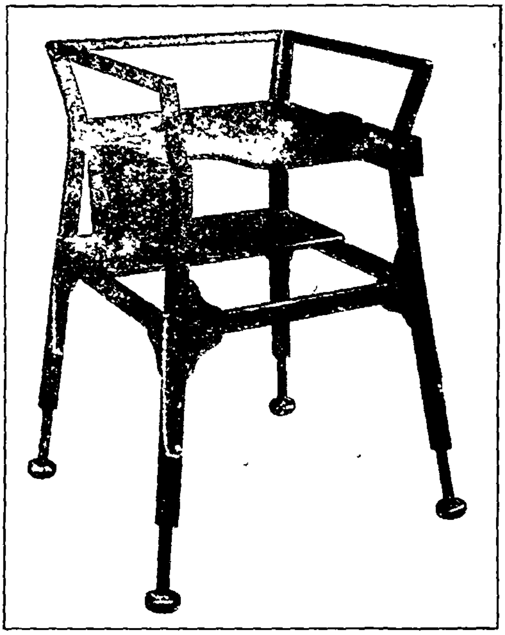
COATS, GOWNS, AND SMOCKS.

IMPROVED patterns in white drill coats and gowns for doctors and dentists are now available. Messrs. E. and R. Garrould, Ltd., supply a smock overall with short sleeves, which can be used where a full-length operating gown is not required, and short coats can be had with stand-up or ordinary tailored collars. The dentist's coat has removable buttons down the side and a belt at the back only. The operating gown can be supplied not only in white drill but in sterilisable waterproof material.

Dr. W. BENTON (M.O.H., East Ham) informs us that the son of a medical practitioner of Vienna, aged 15, who speaks good English, is desirous of visiting England during the vacation, July and August. Board-residence is offered at his home in Vienna suburb, in exchange for the same in or near London, to the son of medical man about the same age. Communications should be addressed in the first instance to Dr. Benton, at the Town Hall, East Ham, E.6.

A WALKING CHAIR FOR CRIPPLES.

In institutions where large numbers of paralysed or disabled children are cared for, it is difficult to ensure that they all have adequate exercise. They are apt to gain weight excessively, and they may become increasingly helpless as they grow older. The difficulty has been met by devising "walking machines" in which the child stands inside a ring mounted on a wheeled frame. Such an arrangement is open to the objection that the occupant has to be lifted in and out of the apparatus at each short exercise, and the construction generally is such that the tendency is to walk in a circular path. Miss Elsie L. Thompson, a nurse at present in charge of crippled children, has designed the combined chair and walking appliance shown in the accompanying illustration. The seat can be raised at will, and the occupant is then able to support himself by the arms and push the appliance in any direction he chooses. Thus he is often enabled to change his occupation—for instance, to fetch fresh playthings or books—without having to get help. The hinged shelf, which forms a table or desk in front of the sitter, can be moved out of the way when the occupant is being put into his seat or taken out of it. The length of the legs can be varied by adjusting the slides and securing them with the locking pins which are attached by chains. The lower part of the appliance is made heavy enough to ensure complete stability. While the whole structure must be readily movable it must not move too freely, and experience has shown that the common type of caged ball rollers form satisfactory feet. Miss Thompson (32, Sherriff-road, London, N.W. 6) has applied for a patent in conjunction with the maker (Mr. H. J. Watson, 71, Fanshaw-street, Hoxton, London, N. 1) from whom the chairs can be obtained.



Vacancies

For further information refer to the advertisement columns.

Altrincham General Hospital.—Sen. and Jun. H.S. At rate of £150 and £120 respectively.
Ashton-under-Lyne, District Infirmary.—Res. M.O. £200.
Battersea B.C.—Res. M.O. for Council's Maternity Hospital, Bolingbroke-grove, Wandsworth. £150.
Bedford County Hospital.—Second H.S. At rate of £110.
Birmingham City, Maternity and Child Welfare Dept.—Four Temporary M.O.'s. £9 10*s.* per week.
Birmingham and Midland Eye Hospital, Church-street.—Tw Out-patient Officers. Each 1 guinea per session.
Birmingham, Queen's Hospital.—Surgeon for Out-patients. £50
Bradford Royal Infirmary.—H.P. and H.S. Each at rate o £135.
British Solomon
Burton-on-Trent, nd H.P. £150.
Canterbury, Ke *Chartham.*—Jun Asst. M.O. £350.
Cardiff, City Lodge Institution.—Asst. M.O. £150.
ond H.S. At rate of £15

"FALLEN IDOLS."

THE CASE OF APPENDICITIS.*

BY SIR JAMES BERRY, F.R.C.S. ENG., D.C.L.,

CONSULTING SURGEON AND EMERITUS LECTURER ON SURGERY TO THE ROYAL FREE HOSPITAL, LONDON.

FROM the point of view of the patient I sometimes doubt whether the progress of surgery has always been as beneficial as it should have been. Let us take the case of appendicitis. An idol that seems to be worshipped to-day by the majority of our profession, to say nothing of the general public, is the view that acute appendicitis is a terribly fatal disease and that it must be treated by immediate operation whenever possible. A wise old physician, universally respected, and now on the consulting staff of one of the larger London hospitals, and some years my senior, remarked to me only a few years ago, "I think the medical profession has gone quite mad about appendicitis," an opinion with which I cordially concurred. Some months ago I said to a friend of mine, a thoughtful well-informed middle-aged surgeon, attached to one of the London hospitals, "Surgeons nowadays seem to look upon most cases of acute appendicitis as they would upon a case of strangulated hernia, as cases that will die if not at once operated on." And his reply was "Well, is it not so?" Then I put to him this question: "In one year at St. Bartholomew's, in the days when I was house surgeon and house physician, long before the time of frequent operations, 31 patients were admitted to the medical wards with appendicitis, or perityphlitis as it was then called. They were mostly rather bad cases, with considerable swelling in the iliac fossa. Of these 31 cases, how many do you suppose died?" His guess was "something between a quarter and a third," and he was greatly surprised when I told him that the actual number was "one."

Since then I have put the same question to many others of my friends both medical and surgical, and most of them made guesses similar to the above; in one instance the answer was actually one half. The wise old physician already mentioned who had intimate knowledge of those early days, although himself attached to another hospital, was the only one who made an approximately correct guess by answering "two." I do not want to make too much of a single incident like this, drawn from a time when hospital statistics of appendicitis were by no means so accurate as they should have been, but there can be no doubt that in the minds of most of the younger doctors of the present day there is a grossly exaggerated idea of the mortality of acute appendicitis, when it is properly treated on common sense lines, and not necessarily by operation.

MORTALITY FROM APPENDICITIS IN THE OLD DAYS.

It is of course very difficult if not impossible to ascertain what was the real mortality of appendicitis in the old days when it was treated mostly by non-operative measures. A certain proportion of cases ended fatally, but such evidence as I have been able to get shows that it was not a very large proportion; and this is in accordance with my own recollection of those early days. An old friend of mine who has only recently retired after long years of general practice in a small midland town and surrounding country has recently reminded me that some 20 years ago he had asked me to give him directions how to treat his appendix patients when he saw them at the beginning, in their own homes. I had given him what I should call the usual common sense directions on what many would call old-fashioned lines, and he has followed them implicitly. He now tells me that he has never had a patient operated upon in the early stages of an attack and that he has never had a death from appendicitis in his practice during all these years.

There are but few, if any, English counties in which I have not at one time or another stayed in the houses of country doctors and discussed with them the problems of appendicitis. I have talked to many sensible thoughtful country practitioners both young and old, who have ridiculed the idea that appendicitis if properly treated without early or extensive operation *is a very fatal disease. The older men, those* brought up in the days when hospital physicians had much practical experience of appendicitis and gave sound teaching in its treatment, did not as a rule regard it as a very serious disease or find that operative treatment was very often required. All over the country there must still be hundreds of doctors, able thoughtful experienced men, who know as well as I do that appendicitis if properly treated from the beginning, and throughout the illness, by absolute rest in bed, by starvation, and by avoidance of all purgatives and enemata, is a disease of very low mortality; who know that it is only in a small minority of cases so treated that any abscess will form; that if an abscess does form it is better not to be in too great a hurry to open it, but to wait, watch, and exercise a wise discretion in the choice of how and when to operate.

Indeed I have heard it said, long ago, by experienced men well qualified to judge, that in such circumstances there was no mortality. And there was but little exaggeration in this statement. It is incorrect treatment, active injudicious treatment whether medical or surgical—for one may be as bad as the other—that does so much harm in acute appendicitis. If the operator is inexperienced there is to the patient much more danger in opening an appendix abscess prematurely and in the wrong way than there is in leaving it even to the point of allowing it to burst spontaneously, although this, I need hardly say, is not to be desired. Operations done when the abdomen is distended even when done by skilful surgeons, unless they have had much experience of appendicitis operations, are seldom worth doing. Such operations will save a life occasionally. In the majority of cases they deprive the patient of his last chance of life.

THREE PRINCIPAL CAUSES OF DEATH.

In the olden days, when patients were sometimes treated medically by too active treatment, on the ground that "you must do something, you know," there were, in my opinion, three principal causes of death.

1. Feeding the patient when he should have been starved.

2. Giving purgatives and enemata to get the bowels opened when it was of the utmost importance that they should be kept absolutely at rest so long as there was any risk of abscess forming.

---

* Part of the 157th Annual Oration delivered before the Medical Society of London on May 9th.

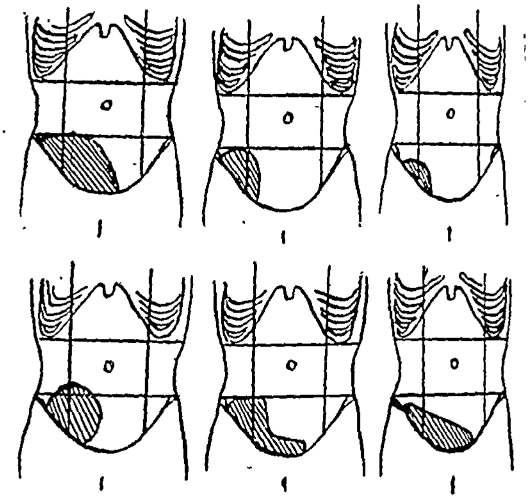
3. Attempting by means of drugs or otherwise to relieve the abdominal distension, which is protective and curative and not, as is so often thought, harmful in itself. Distension is often a grave symptom, but its sudden removal is often much more grave.

A striking instance of the evil effects of suddenly getting rid of distension occurred in the case of an old gentleman whom I saw in the country not many years ago. When I was first called to him there was already very great abdominal distension and the patient was much too ill in my opinion for any operation to have any chance of success. The doctor with whom I saw the case fully agreed with me. For several days he gradually got better; all the more acute symptoms subsided but the abdomen remained much distended and the bowels were not opened. There was no vomiting. Both the doctor and myself knew that the patient was getting well, but the patient's relatives were restive. To satisfy them, a well-known surgeon, a few years older than myself, was called in with my consent, but in my absence. He agreed that no operation was desirable, but unfortunately yielded to the friends' entreaties and, against our wish, prescribed remedies to relieve the distension. The bowels were freely opened, the distension disappeared, but the patient died of collapse a few hours later. There was no post-mortem examination, but there can be no reasonable doubt that this valuable life was thrown away by ill-advised interference. It is one of the very few cases of appendicitis that I have ever lost.

DANGERS OF FREE INCISION.

I am far from presuming to teach hospital surgeons who have had large experience and possess much operative skill in dealing with acute appendicitis. I know that there are numerous general practitioners of much experience and skill in such operations who have an advantage denied to most consulting surgeons in that they see their appendicitis cases earlier than do most hospital surgeons. These also I do not presume to teach. They often obtain admirable results in operating upon really early cases, and it is for them to judge whether the operation is or is not necessary. But this I do know, that anyone, be he general practitioner or hospital surgeon, who blunders into an appendix abscess without knowledge of the pathological condition which he may expect to meet with, and without taking the precaution either to limit his incision to the area guarded by adhesions or otherwise to prevent the diffusion of pus into the surrounding non-adherent peritoneal cavity, is courting disaster. When surgeons say and write, as they often do, that in the opening of an appendix abscess it is immaterial whether this be done through limiting peritoneal adhesions or through the unobliterated peritoneal cavity, they are talking dangerous nonsense. It is just the want of attention to this very point that is a fertile cause of disaster. This I pointed out in two letters to THE LANCET[1] 32 years ago, giving as I thought ample evidence of the truth of what I then stated. In one of these letters I gave statistics, from my own observations and knowledge, of 2 deaths only among 41 cases of abscess opened by incision through adhesions, and of 32 deaths among 39 patients treated by free incision into the general peritoneal cavity, an operation which was then beginning to become fashionable and which is now so common.

I do not claim that the two classes of case are in every respect strictly comparable, but approximately they are representative of the two widely different methods of treating appendicitis by two sets of surgeons in the same hospital in the 'nineties and also at the present time. In the same letter I published the six drawings here reproduced, all of which were drawn by myself in the post-mortem room of St. Bartholomew's from the bodies o actual patients who had died after operations i which no attention had been paid to limitin adhesions. I was comparatively young, only 3 and quite unknown, when I wrote those two lette in which I first strove to stem the rising tide reckless operating that I saw surging all around m Some two years later (1902) Treves gave his celebrate Cavendish lecture.[2] It is a classic that should read by everyone. It is full of practical and usef information as to the pathology, diagnosis, an treatment of appendicitis. Treves wrote, as I di from observations made in the post-mortem room well as in the operating theatre. One passage fro that lecture, rarely if ever quoted nowadays, is great importance:



Drawings of six fatal cases of appendicitis showing the exact area of pus or adhesions in contact with the anterior abdomina wall. All of these had been operated upon by incisions withou regard to the areas of adhesions. It is possible that timel incisions limited to the areas of adhesions might have save all these patients.

"There are advocates of what may be called ind criminate operation. They use terms of this sort—'Y must operate; the appendix is ruptured; there is perforation; there is acute peritonitis; there is gangren And mark—and this is the point I want to draw attenti to—these expressions are used exactly in the same sen as you use such expressions as 'There is a perforation the bowel; there is a perforating ulcer of the stomac there is gangrene or hernia of the intestine.' And so th say an operation must be carried out even before a reasonal diagnosis has been made, as soon as an attack is suspect

"What I very seriously object to is this: that the t things are put in the same category. It is an absolut false analogy and misleading. Is it for one moment reaso able to put perforation of the appendix in the same catego with perforation of the stomach? It is monstrous. only can a perforation of a fair size occur in the appen but a fair degree of gangrene may be met with with causing serious symptoms. I have found a concret lying outside the appendix one month after an atta when all the symptoms have subsided and without a sin drop of pus."

Thus spoke Treves, from his own observatio From my own post-mortem observations I can ful confirm the truth of what he says. In the de body of a person who had died of a totally differe disease, I have myself seen an appendix the midd third of which had been completely destroyed gangrene many years previously. It was represent erely by a slender fibrous cord. And yet there had ever been an operation and if there had been an bscess, as was probably the case, it had been mpletely absorbed without discharging either ternally or internally. Such is the marvellous cuperative power of the peritoneum.

Two Historic Cases.

Let me tell you of two great historic cases of ppendicitis separated from each other in point of ime by nearly a quarter of a century. I know nough of surgical statistics to be aware that two solated cases by themselves prove nothing, but I hoose these two cases because they are, in my pinion, quite typical of the two modes of treating cute appendicitis which I want to contrast. I could relate equally well many similar cases of both kinds which I have seen myself, either in my own practice or in the practice of others, but for my present purpose. which is to illustrate how fashions change in surgery, these two cases are the most striking that I can give you. Both are world famous and the first had a great influence in spreading among the public the modern popular view about operations for appendicitis. a disease of which the public up to that time (1902) had scarcely even heard.

1902.	CASE 1.—AGED 61.
Saturday, June 14 ..	Abdominal discomfort.
Sunday, „ 15 ..	5 A.M.: Seen by doctor for *acute attack of pain.*
	Afternoon: Seen by consulting physician. ? Rigor.
Wednesday, „ 18 ..	*First seen by surgeon.* Temperature. Pain and swelling in right iliac fossa. Diagnosis "perityphlitis" (i.e., appendicitis).
Thursday, „ 19	Above signs disappearing.
Friday, „ 20	
Saturday, „ 21 ..	Seen again by surgeon. Swelling nearly gone. Temperature normal.
Monday, „ 23 ..	Seen by surgeon.
Tuesday, „ 24 ..	OPERATION. Limited incision into intraperitoneal abscess. Much foul pus drained. Appendix not removed, not seen, not felt.
Afterwards ..	.. No recurrence. Lived nearly eight years.

1925.	CASE 2.—AGED 54.
Sunday, Feb. 22 ..	Very well all day.
Monday, „ 23 ..	In night slight abdominal pain.
	9 A.M.: Seen by doctor.
	5.30 P.M.: *Severe abdominal pain*, doctor sent for.
	6 P.M.: Tenderness and slight rigidity in right iliac fossa.
	9 P.M.: First seen by surgeon. Immediate operation to be done. Moved to nursing home.
Tuesday, „ 24 ..	12 midnight: OPERATION. Free incision into peritoneal cavity. Removal of appendix. Turbid non-odorous fluid. Intestines distended. Pelvis quite free from fluid.
Saturday, „ 28 ..	Death. Post-mortem examination.

Both patients were treated, as was but natural in the case of such important personages, by famous surgeons of very large experience, probably the best surgeons that could be found in either country. I need hardly say that no shadow of blame could be attached to either of them. Each undoubtedly treated his patient by the method which he thought was best, and in both instances the operative treatment adopted, although widely different in the two cases, was in accordance with prevalent surgical opinions at the respective dates.

I.

Of the first case I can tell you something which is apparently not generally known by the present generation of medical men, still less by the general public. It has been well known to me for 30 years. and after this long lapse of time, I think that in the public interest it is only right that it should be known. I have not the slightest doubt that H.M. King Edward VII. owed his life to the wise discretion and skilful treatment, perhaps I should rather say the wise avoidance of any active treatment by his advisers, both medical and surgical, until the right time was judged to have come for surgical interference. And mark you, this right time was nine days after he had been first seen by the attending physician, and no less than six days after he had been first seen by the operating surgeon, six days after the time when on June 18th (I quote from the more or less official report) "the temperature was [then] elevated, there were swelling and tenderness in the right iliac fossa—in short there were symptoms of perityphlitis." I should like to ask you how many enthusiastic surgeons at the present day under the influence of the prevalent modern teaching would have refrained from operating at this much earlier period. As might have been foretold by anyone of much experience, and doubtless was foretold by the wise men under whose care he was, these acuter symptoms subsided; later the King was brought to London and next day, not the same day, an operation—as all the world soon knew—was performed upon him. Within a few hours of the performance of this operation I received a full account of it from one of the Serjeant Surgeons who was present and who saw exactly what was done. Later I received corroborative testimony from one of the physicians who was also present.

And what was the operation? All the world knew that it was an operation for appendicitis, that the King made a good recovery and that he lived nearly eight years longer and that he never had any recurrence. Few people knew even at that time that the appendix was not removed, that no search for it was ever made, that it was neither seen nor felt. A careful incision was made low down until an abscess was reached and opened; tubes and gauze were inserted and nothing more was done. What would have happened had this case occurred 25 years later, under the influence of the modern teaching that an appendicitis patient should be operated upon as soon as he is seen by the surgeon and the sooner the better? Who can doubt that most enthusiastic modern surgeons if they had followed their own teaching would have opened the abdomen freely, that the appendix would have been removed. or that, at any rate, an attempt would have been made to remove it. After a large experience of cases that I have seen, treated by both methods, and still more that have been related to me, I have but little doubt that the patient would have had little chance of surviving as long as eight days, to say nothing of eight years.

There is no little irony in the fact that the popularity of the modern operation of treating appendicitis by free incision and removal of appendix and abscess without regard to limiting adhesions is largely based upon ignorance of what was really done at this famous operation.

II.

Let us turn, by way of contrast, to the second case. Twenty-three years have elapsed. surgical fashions have changed. The septic focus, this dangerous appendix, must be removed at the earliest opportunity, and at any cost. Surgical technique has greatly improved, it is true, but the disease called

3. Attempting by means of drugs or otherwise to relieve the abdominal distension, which is protective and curative and not, as is so often thought, harmful in itself. Distension is often a grave symptom, but its sudden removal is often much more grave.

A striking instance of the evil effects of suddenly getting rid of distension occurred in the case of an old gentleman whom I saw in the country not many years ago. Later I received corroborative testimony from one of the physicians who was also present.

And what was the operation? All the world knew that it was an operation for appendicitis, that the King made a good recovery and that he lived nearly eight years longer and that he never had any recurrence. Few people knew even at that time that the appendix was not removed, that no search for it was ever made, that it was neither seen nor felt. A careful incision was made low down until an abscess was reached and opened; tubes and gauze were inserted and nothing more was done. What would have happened had this case occurred 25 years later, under the influence of the modern teaching that an appendicitis patient should be operated upon as soon as he is seen by the surgeon and the sooner the better? Who can doubt that most enthusiastic modern surgeons if they had followed their own teaching would have opened the abdomen freely, that the appendix would have been removed, or that, at any rate, an attempt would have been made to remove it. After a large experience of cases that I have seen, treated by both methods, and still more that have been related to me, I have but little doubt that the patient would have had little chance of surviving as long as eight days, to say nothing of eight years.

There is no little irony in the fact that the popularity of the modern operation of treating appendicitis by free incision and removal of appendix and abscess without regard to limiting adhesions is largely based upon ignorance of what was really done at this famous operation.

II.

Let us turn, by way of contrast, to the second case. Twenty-three years have elapsed, surgical fashions have changed. The septic focus, this dangerous appendix, must be removed at the earliest opportunity, and at any cost. Surgical technique has greatly improved, it is true, but the disease called appendicitis remains what it has always been, even when it was not known by that name.

Another ruler of a great European State, President Ebert, also an oldish stout man, but seven years younger than the first, is on a certain Sunday (Feb. 22nd, 1925) in his usual health. In that Sunday night he felt a dragging pain in the abdomen of which he told his doctor, when next morning (Monday the 23rd) the latter paid a casual visit that had been arranged some days before. At 5.30 P.M. there was more pain; at 6 P.M. the doctor found marked tenderness in the cæcal region with slight rigidity. At 9 P.M. the patient was first seen by the surgeon, a university professor, a man of world-wide fame, one of the most celebrated and experienced in his country. On the ground of the local condition, and because it was considered to be an early operation (*Früh-Operation*) it was agreed that an immediate operation was required. The patient was removed to a nursing home and at midnight, that is, only three hours after he had been first seen by the surgeon, a free incision was being made into the abdomen and the appendix was removed together with much non-odorous purulent fluid. The intestines were much distended and it is expressly stated that the pelvis was quite free from fluid. For a day or two the patient seems to have done fairly well. Then distension, rapidity of pulse, restlessness, sweating, and so forth set in and on the sixth day (Feb. 28th) the patient died.

As I read the full and detailed original official account of this modern "early" operation, now so fashionable, when it was first published[3] I could not help feeling that I was back again in the good old days at St. Bartholomew's in the 'nineties. Back in the days when I, as *surgical registrar*, was myself seeing such things done and recording them in the post-mortem book and in my annual surgical reports.

Hospital Experience.

I have no reason to suppose that the treatment of appendicitis at St. Bartholomew's in the 'nineties differed materially from that which pertained at most other London hospitals at the same period. Corroboration of this view seems to me to be afforded by the admirable paper[4] published in 1904 by Cuthbert Wallace and Percy Sargent which gives details of all such cases treated at St. Thomas's Hospital during the ten years ending December, 1903.

Although I differ from them in some of the conclusions they drew from these cases, I cannot refrain from expressing my appreciation of the great value of this and similar reports based on the careful and detailed study of large numbers of cases. I wish very much that I had written a similar report on the cases that were under my observation at St. Bartholomew's at much the same period, instead of publishing them merely in the obscure and seldom read appendices to the statistical tables of that hospital. St. Thomas's has long been famous for the excellence of its abdominal surgery, and, if I may be permitted to say so, its reputation in this respect has recently been well maintained by a second equally admirable paper[5] published by B. R. Sworn and G. M. Fitzgibbon, another pair of surgical registrars at this same hospital. This latter paper is on the same lines as that of their distinguished predecessors, and deals with the ten years 1920 to 1929, inclusive.

Without entering into any discussion of the conclusions arrived at by the authors of these papers, I should like to draw attention to the facts contained in Table III. of the second paper and to the third conclusion which is that "if a palpable mass is present the best results are obtained by conservative treatment, where this is possible." This seems to me to be a notable advance on much of modern teaching.

I do not wish to discuss the question of removal of the appendix in a quiet interval. We all know that it is an excellent operation, although we also know that it is performed much too frequently and very *often when there is nothing at all the matter* with the appendix. Nor do I wish to say anything about the much discussed question of operating in the very early stage of acute appendicitis, an operation which is so fashionable at the present day. Personally I seldom see cases at this very early stage and when I do see them I rarely find it necessary to operate upon them. Throughout my life I have adopted the plan of not being in any hurry to operate, except in very rare and exceptional cases. Never have I had any reason to regret this practice.

I have been told that appendicitis is more common than it used to be; it has also been suggested to me that the type of infection has become more virulent. I can find no evidence for either of these statements and I do not believe them to be true. That the disease is recognised and diagnosed more frequently, and that active treatment is adopted far more often, there can of course be no shadow of doubt. That deaths are more common now than formerly is apparently an undoubted fact. According to the Registrar-General's latest published statistics the total deaths from appendicitis in England and Wales for the year 1930 were 2941.

It is not improbable that I shall be blamed for having again brought forward these views about the treatment of appendicitis. I shall probably be told that I am old-fashioned, not up to date, or that I am trying to set the clock back. I should maintain on the contrary that I am trying to introduce a little more sanity into the present-day treatment of acute appendicitis, a little more discrimination and judgment in the choice of operation, and when and how it should be performed when it is really necessary, a little less reliance on the hard-and-fast rule, adopted by so many, of operating at any and all stages—a rule so easy to follow, but often so disastrous to the patient.

I have spent half a century in watching and studying appendicitis in all its various moods and forms. I have seen nearly every form of treatment from the simplest to the most heroic. I do not believe that I can be wrong in my conclusions, I can only tell you what I believe to be the truth. Looking around me I am inclined to say that the prevalent surgical treatment of appendicitis, though still holding the position of an idol, is an idol whose pedestal is beginning to totter.

KING GEORGE HOSPITAL, ILFORD.—In 1931 the income was £20,303, and the year closed with a credi balance of £22. Thanks to the extension opened by the King last summer, the beds have been increased from 74 to 130, and the average daily number of in-patients consequently went up from 66·75 in 1930 to 97·56. On the average they remained for nearly three weeks; the average cost per bed was £3 5s. 2d. There were 7657 out-patients at Ilford and 6180 at the Becontree centre and, together, there were more than 61,000 attendances as compared with a total of 4000 patients and 12,130 attendances in 1930. In-patients increased by 107,—

THE MODE OF ACTION OF VITAMIN D.

THE "PARATHYROID" THEORY: CLINICAL HYPERVITAMINOSIS.

By Leslie J. Harris, D.Sc., Ph.D.

(From the Nutritional Laboratory, University of Cambridge and Medical Research Council.)

Reference has been made in recent articles[1] to two important questions, the first of fundamental theoretical interest, the second of more immediate practical concern. Firstly, does vitamin D act by stimulating parathyroid function? Secondly, what danger is there of hypervitaminosis being induced clinically? Although these questions are still freely debated, it is my opinion that recent work has gone a long way towards providing reasonably definite answers to them both, and it may prove useful to summarise the evidence in bare outline.*

Action of Vitamin.

A review of the literature relating to vitamin-D deficiency, published several years ago,[5] led to a view of vitamin D action which has more recently been substantiated by intensive studies on the effects of vitamin excess, carried out in the Cambridge Nutritional Laboratory. Arguments deduced from vitamin deficiency may be summarised first.

PATHOGENESIS OF RICKETS.

In vitamin-D deficiency in humans or in experimental animals, as has been repeatedly shown, there is inadequate utilisation of the food calcium, or phosphate, or both, or, more correctly, an increased loss in the fæces. It may be that too little Ca and/or P is absorbed from the gut, or alternatively that too much is re-excreted back into the gut: possibly both mechanisms are involved—the evidence does not permit a definite decision at present—but we are entitled to say that the *net absorption* is decreased in vitamin-D deficiency.†

The inadequate net absorption can next be correlated with a deficient level of one or both of these elements in the blood stream. This diminution in the blood Ca or P, or the Ca × P product, is the real immediate cause of the bony irregularities and the clinical manifestations; so that rickets is aptly described as essentially a disease of the blood rather than the bone. Most frequently, actually, it is the blood phosphate and not the calcium which tends to be low in clinical rickets (low-phosphate rickets), but low-calcium rickets has also been described and readily produced experimentally; a low blood calcium in the avitaminosis is the cause of tetany. In *juvenile* and *adult rickets*, too, the pathogenesis is the same—viz., inadequate net absorption of Ca and/or P, hypophosphatæmia and/or hypocalcæmia, and hence a resulting defective calcification of newly forming bone tissue (or a similar net loss of mineral matter from fully grown bone, which is to be recognised not as a static but as a dynamic structure continuously gaining and losing mineral salts).

It is important to realise that deficient calcification in newly forming bone tissue follows necessarily whenever the blood Ca × P is low. Once we restore sufficient vitamin D to the diet, the net absorption improves, the hypophosphatæmia (or hypocalcæmia, whichever is at fault) is rectified, and consequently adequate calcification can now once again take place, so that evidence is seen of healing of the rickets (or there is cure of the tetany). The brilliant experiments of Shipley[6] and Robison[7] and their co-workers show that the same considerations apply to the calcification of bone in vitro.

A slice of defectively calcified rachitic bone will recommence to calcify normally when it is placed in saline having an adequate Ca × P product, or in serum from a normal animal—i.e., with the normal Ca × P product—but it fails to calcify when the Ca × P is low, as in serum from a rachitic animal. In other words, the extent of calcification is governed by the Ca × P product of the fluid medium bathing the bone.

The exact mechanism concerned in the actual precipitation of the calcium from the blood into certain sites in the bony tissue we know to depend, inter alia, upon the presence in the latter of an enzyme, phosphatase,[8] whose activity, be it stressed, remains fully normal in rickets.[9] Whatever may be the complexities of the calcifying mechanism itself, we may conclude that the error in rickets is not primarily in the bone but in the inorganic composition of the blood, and that vitamin D has the appearance of increasing the concentration of Ca and/or P which can be carried in the blood stream.‡

Admittedly the theory of vitamin D action outlined above has not yet won general acceptance. The orthodox continental view is that vitamin D acts directly on the bone; and no less an authority than Alfred Hess (for example) concludes that in spite of much experimentation no answer can yet be given to the question, why rachitic bone remains uncalcified, that the metabolic work on infants suffering from rickets presents a "mass of material that it is impossible to appraise," and that the main action of vitamin D appears to be other than on gut absorption of Ca and P.[10] But the theory accounts so consistently not only for the facts already mentioned but also for the phenomena of hypervitaminosis (see below) and for a further variety of observations now to be mentioned, that in my opinion little doubt can remain as to its essential correctness.

INFLUENCE OF FACTORS OTHER THAN VITAMIN D.

Obviously enough, for the vitamin to be effective in procuring an adequate net absorption of Ca and/or P there must be a sufficiency, absolute or relative, of available calcium and/or phosphate in the gut. Therefore, additional factors which must also to a large extent influence the net absorption (and the blood figure, and hence the consequent calcification) are the following: the Ca and P content of the diet; the Ca–P ratio of the diet (this affects the solubility of the Ca salt, and hence the ease of absorption); the acid-base ratio (which also governs the solubility, under certain conditions), &c. A high-Ca low-P diet will tend to produce hypophosphatæmia, and hence low-phosphate rickets, while a low-Ca high-P diet will tend towards hypocalcæmia and low-calcium rickets. All these expectations are borne out by the observed results.

Several puzzling observations may perhaps be explained upon the lines of the general theory given in the foregoing discussion.

(1) For example, it has been shown that in experimental low-phosphate rickets a change to a diet richer in phosphate will suffice to bring on sudden tetany. It suggests itself to the writer that the explanation here may be simply as follows: the provision of extra phosphate will force up the level of the phosphate in the blood; and, since we are to suppose that the deficiency of vitamin D keeps the Ca × P product low, it follows that the Ca must become

---

* The details of the experimental work principally referred to in the present paper, together with an extended bibliography, were given elsewhere (Harris and Innes, 1931[2]: see also earlier papers[3, 4]).

† *Net absorption.* I have suggested[2] the use of this expression for denoting the intake minus the fæcal excretion. It is, of course, a measure of the gross absorption less the amount re-excreted back into the bowel.

P for brevity, denotes *inorganic* phosphate, not total phosphorus.

‡ The direct addition of irradiated ergosterol to serum in vitro does not suffice to increase the amount of calcium and phosphate which can be dissolved in it, according to unpublished work by the writer.

relatively depressed, and so tetany will ensue. (Other things being equal, a rise in blood P is accompanied by a fall in Ca, and vice versa.)

(2) Again, it is known that in low-phosphate rickets simple starvation may suffice to bring about evidence of healing in the rickety bone. In this case the explanation may well be that the blood phosphorus becomes raised as a result of the breakdown of organic phosphorus of the tissues and so gives rise to the observed calcification.

(3) Finally, an explanation may be sought for the observation that whereas in humans or dogs simple deprivation of vitamin D suffices to bring on rickets, in rats it is necessary to disturb the salt balance as well. There can be *little doubt that here the explanation lies in the exceptional power of the rat to make full use of any calcium or phosphate obtained in its diet.* Direct measurements show that whereas with either the dog or the human the utilisation of normal amounts of Ca and P becomes vanishingly small in the absence of vitamin D, with the rat the utilisation still remains comparatively good. Hence we can understand why it becomes necessary in order to secure frank rickets in the rat to upset the salt balance in addition; by so doing one is putting a further obstacle in the way of adequate absorption—e.g., in the case of the high-Ca low-P rachitogenic diet by rendering the Ca and P relatively insoluble.

HYPERVITAMINOSIS D.

Studies in the Nutritional Laboratory during the past three and a half years on the effects of vitamin D excess have served to substantiate the views summarised above as to the nature of vitamin D action. They have also provided a rational explanation of the nature of the ill-effects seen in the hypervitaminosis.

The empirical fact that excessive doses of irradiated ergosterol are toxic was first recorded by the German observers Pfannenstiel [11] and Kreitmair and Moll,[12] the latter drawing attention to the presence of calcium deposits in the soft tissues; but they were unable to throw any light on the meaning of the toxicity, suggesting only that the loss in weight of the experimental animals seemed to indicate an increased basal metabolic rate,[12] and that the lesions might be compared with cholesterol arterio-sclerosis. I predicted that the effects of vitamin excess would be found to stand in logical contrast with those of a shortage, the mode of action of the vitamin in excess being essentially an intensification of its normal action when given in small amounts. We wrote [3]:

> "It would appear that there are low and high threshold values for vitamin D, below and above which there are caused deficient and excessive values respectively of blood phosphorus and/or blood calcium and resulting calcification."

A considerable amount of experimental work has served to confirm this view. Summarising our results in other words, we have shown that just as vitamin-D deficiency causes inadequate net absorption, low blood Ca and/or P, and resulting inadequate calcification, so vitamin D excess, on the other hand, brings about a greatly increased net absorption,[2] a tendency to hypercalcæmia and/or hyperphosphatæmia,[2, 4] and excessive formation of densely calcified new bone.[2, 13] These experimental results were interpreted as follows [2]:

> "An increased vitamin D intake promotes increased absorption of Ca and/or phosphate from the gut (or diminished excretion into the gut), so tending to raise the level in the blood. With inadequacy of vitamin D, the blood fails to secure sufficient Ca and/or phosphate; with moderate amounts the blood succeeds in maintaining its approximate constancy of composition, while with large overdoses, hypercalcæmia and/or hyperphosphatæmia cannot be averted."

The overcalcification of bone is strikingly shown by radiogram or histological section (Figs. 1 and 2); the excessively densely calcified spongiosa are seen reaching far into the marrow cavity.‖ Analogous changes occur in the teeth; the cement becomes overcalcified and a remarkable overgrowth of cementoid is formed, which may become ankylosed to the alveolar bone; abnormal new deposits of dentine are put down (Fig. 3). Extensive metastatic calcium deposits are also found in the soft tissues, as originally noted by Kreitmair and Moll,[12] notably in the kidney and in the artery walls (particularly the aorta). There seems little doubt that these are due to the precipitation of the calcium salts from the *highly saturated blood, and must be ascribed directly* to the hypercalcæmia and/or hyperphosphatæmia per se, for the same result accrues also whenever the blood calcium or phosphate is raised to abnormal levels by other means—e.g., by administration of excessive calcium and phosphate, or by means of parathormone (see below). It is worthy of note that the kidney should be one of the sites most liable to receive massive calcareous deposits; and although admittedly this may be favoured by the immensely increased concentration of calcium salts passed through the organ, it can scarcely be without significance that the kidney is known to be richly provided with phosphatase, the enzyme which in bone is concerned in the process of depositing calcium. In fact I am informed by Dr. Robison that the kidney and the aorta among the soft tissues are exceptionally rich in phosphatase, and these, it will be noted, are the very sites which (after the bone) become most extensively calcified in hypervitaminosis.§ To complete our comparison between vitamin excess and deficiency, it may be mentioned that even the muscles have been shown to have an abnormally high Ca or P content in hypervitaminosis, contrasting with the deficiency common in rickets.

It has been shown further by the Cambridge workers that as the hypervitaminosis *proceeds*, abnormally large amounts of phosphate and calcium are excreted in the urine.[3, 4, 14, 15] This, we would suggest, is readily accounted for as the natural response of the kidney, tending as it does towards riddance of the excess present in the blood, and here once again the same effect is seen in hyperphosphatæmia or hypercalcæmia induced by other means.

It was anticipated that the effects of vitamin D when given in excess would depend largely upon the Ca : P intake just as they do with minimal allowances of the vitamin and in hypovitaminosis. This has proved to be so. Each increase in the amount of calcium in the *diet results*, we find, *in an increased severity* of hypervitaminosis, for any given overdose of vitamin D.[2, 16] This is the result to be expected: the greater the amount of Ca actually available for absorption the greater will be the ill-effects of excessive absorption and the attendant hypercalcæmia. This observation of course provides only indirect evidence of the action of vitamin excess upon net absorption; but direct measurements have been made to establish the issue beyond doubt. It is of interest to note (see Figs. 4 and 5) how clearly each extra addition of vitamin D to a diet tends steadily to raise the net absorption, while *if the excess* vitamin is suddenly withheld the diminution in net absorption which is to be expected on the basis of our theory sets in with dramatic intensity (Watchorn[15]), so tending to alleviate the effects of the hypervitaminosis.

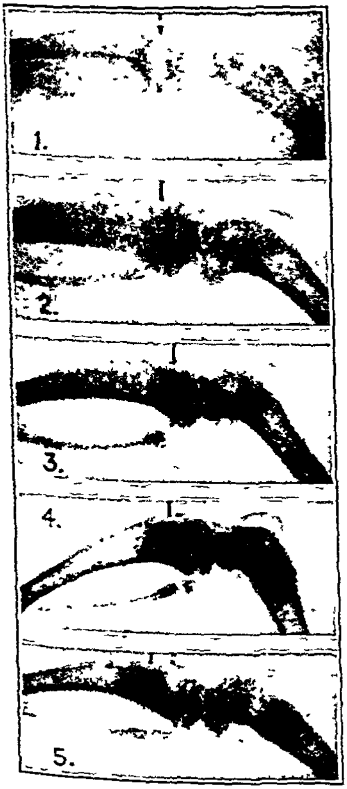
‖ With excess vitamin D osteogenesis is greatly increased, but I have suggested that this does not necessarily indicate any direct action of the vitamin upon the bone cells, for one may imagine that the formation of new bone is stimulated by and dependent on the previous calcification of the osteoid.

§ The presence of phosphatase in such tissues as kidney may possibly occasion surprise, but it must be realised that the "function" of the enzyme is to convert *organic P into soluble inorganic phosphate—an action* which clearly might there serve a useful purpose—and that under more normal conditions the secondary effect, the precipitation of calcium salts, would not be involved in sites outside the bone.

Many of the findings first reported from this laboratory, such as the raised blood calcium or phosphate, the increased urinary excretion, the excessive calcification of bone, and the influence of the Ca : P intake, have now been repeatedly confirmed by workers elsewhere, and there can be little doubt about the reality of the phenomenon of hypervitaminosis. The suggestion that the toxic action was due not to vitamin D but to the presence of toxic by-products—produced, it was claimed, when irradiation was carried out by the commercial German method in alcohol but not by the English method in oil[17, 18]—has not been substantiated. The German workers Holtz[19] and Windaus[20] supposed the toxic "calcifying" substance to be different from the antirachitic, but no one has succeeded in obtaining a preparation which is antirachitically active and at the same time free from the characteristic toxic effect when given in excess.¶

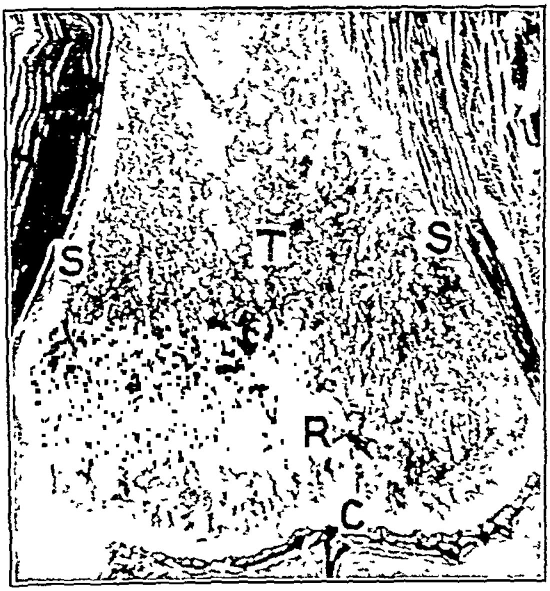
Additional unpublished work is in good conformity with theory. Thus while the administration of vitamin D excess appears to have little or no significant influence on the phosphatase activity of the bones, experiments in collaboration with Dr. Robison show that the hypercalcæmic or hyperphosphatæmic serum of rats suffering from hypervitaminosis will induce an abnormally heavy calcification in bone slices in vitro—no such stimulation of calcification has been demonstrated for the vitamin itself acting direct upon the bone. As to the increased net absorption caused by vitamin D, the importance of excretion into the gut, as compared with absorption from the gut is being further studied. Whether the increased net absorption means that the vitamin acts in any primary sense upon gut function cannot be guessed without further work: diffusibility through the gut wall as affected by vitamin D is now being examined.

FIG. 1.



Radiograms of knee-joints of rats: rickets, normal and hypervitaminosis. (1) Rickets showing defective calcification at growing end. (2) Normal, adequately calcified. (3) Early stage of hypervitaminosis, showing commencement of excessive calcification at growing end. (4) Same, more advanced. (5) Later stage, complicated by severe illness and cessation of osteogenesis, showing less densely calcified band nearest epiphysis.

FIG. 2.



Advanced stage of hypervitaminosis in growing rat. Distal end of femur (×21), showing excessive bone formation, the spongiosa (T) extending far into the marrow cavity. Secondary resorptive changes are apparent also in the cortex of the shaft (S), and to a less degree in the spongiosa (R) nearest the growth cartilage (C).

SECONDARY CHANGES IN EXTREME HYPERVITAMINOSIS.

Our references above to net absorption in hypervitaminosis relate to the primary effect observed, or to the condition of animals receiving *moderate overdoses* of the vitamin. If, on the other hand, *maximal* toxic overdoses are given, and continued for some time, so that the animal begins to lose weight rapidly, and refuses its food, one can no longer obtain evidence of this characteristic increase of net absorption with increased vitamin intake. This is due partly to the loss of appetite, so that little or no calcium is being ingested, but partly also to the breakdown of gut function which is seen in any animal when gravely ill. Partially starved controls on a diet which is normal in composition and restricted only in quantity show a similar failure in percentage net absorption of calcium or phosphate.[15]

Of greater interest, however, was our observation that when the maximal degrees of hypervitaminosis were reached, and no increased provision of calcium was allowed in the diet, there was, especially, marked evidence of resorptive changes in the bone. Fig. 2 illustrates the resorption of compact bone under such circumstances, and shows how spongiosa which had already become abnormally dense under the action of the vitamin D excess begin later to show a band less densely calcified at the growing end. The latter phenomenon, however, may perhaps be correlated with the general cessation of growth (resulting from the severity of the ill-effects) and the corresponding arrest of new bone formation. The conditions of these resorptive changes, we find, are such as to suggest the possible explanation that the bone is called upon as an additional source of calcium for the blood when the alternative available supply in the gut has become exhausted. We have indeed succeeded in showing that as the calcium in the diet is reduced a relatively greater proportion of the extra calcium drawn into the blood does come from the bone. According to this suggested explanation a sufficient increase in the calcium of the diet ought definitely to prevent any decalcification in the bone. An unequivocal demonstration is difficult, however, because while we find that feeding extra calcium in hypervitaminosis does, as anticipated, increase the severity of the hypercalcæmia and the extent of calcification, the animal now succumbs so much more rapidly to these very ill-effects that a direct comparison of the bony changes is not feasible. There is also the secondary loss of appetite, and the consequent absence of the usual source of available absorbable calcium to complicate the direct comparison.

¶ Our early results led us to conclude that toxicity is an intrinsic property of vitamin D itself if fed in sufficient excess; but we did not rule out the possibility that certain by-products could be independently toxic.[3] Recently I have been able to confirm the toxicity of the pure isolated vitamin D (calciferol) and find indeed that its degree of toxicity is of an order sufficient to account entirely for the whole of the toxicity of the crude irradiated ergosterol from which it is obtained. At the same time however I am able to confirm that a preparation can be derived from irradiated ergosterol, as claimed by Holtz, which produces definite toxic symptoms at a relatively much lower level of antirachitic units. The possibility is being examined that the difference in the size of the toxic dose is due to the more ready absorption of the preparation in question, when given in excess.

Notwithstanding the undoubted intellectual interest of the observation just discussed, it is essential to bear in mind, as we have previously emphasised,[2] that the primary action of vitamin D, which is of normal physiological importance, and which is equally apparent whether the vitamin is given in suboptimal amounts, in optimal amounts, or in moderate excess, is that described in the earlier paragraphs —viz., increased net absorption of Ca and/or P, raised Ca × P product, and resulting increased calcification.

COMPARISON OF ACTION OF VITAMIN D AND THE PARATHYROID HORMONE.

The knowledge that parathormone, like vitamin D, can bring about a rise in the blood calcium has recently led numerous writers to adopt the view that vitamin D acts simply by direct stimulation of parathyroid function. Noel Paton [21] had earlier supposed nutritional tetany to be in every way identical with parathormone deficiency, and Block and Faber [22] had postulated that irradiation (equivalent of course to vitamin D administration) cured tetany by stimulating the parathyroids. Various arguments are given for supposing that rickets and osteomalacia are due to faulty parathyroid secretion, e.g., Mirvish, 1930.[22a] The beneficial effects of cod-liver oil before parathyroidectomy were attributed by Jones [23] to parathyroid stimulation; and similar conclusions have been given by very many others, including notably Greenwald and Gross,[24] and Taylor, Branion, and Kay.[25] He described an experiment by which he claimed to have proved the connexion.[26] He stated that after the parathyroids had been extirpated vitamin D was no longer able to raise the blood Ca. Further experiments have not confirmed this conclusion, for it has been shown that provided a sufficiently large dose of vitamin D be given its characteristic action can still be demonstrated readily enough.

It is our contention that the available evidence indicates rather that the parathyroid secretion and vitamin D normally function separately and independently, their effect on blood Ca (or P) being only supplementary. The fundamental point of difference between the two, we have urged,[2] is that whereas vitamin D improves the assimilation of food calcium and/or phosphate—i.e., it increases the net absorption—no such action has ever been demonstrated for parathormone, which in contrast raises the calcium in the blood solely by withdrawing it from the bone. What little data have hitherto been published suggest that parathormone has but little effect on net

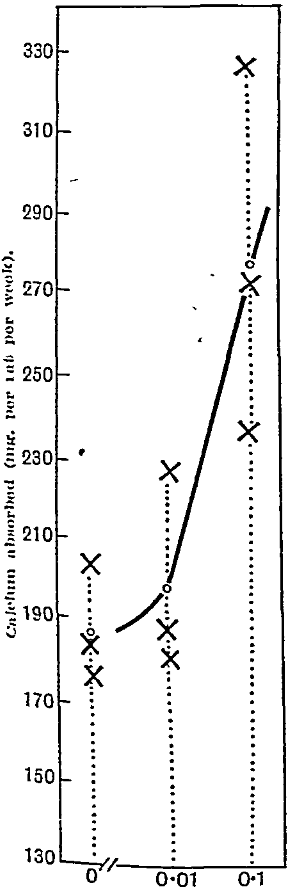
bsorption of Ca and P, and if anything it tends to *liminish* it rather than increase it (see Greenwald and Gross[27]). Whereas the characteristic action of vitamin D in therapeutic doses or moderate excess s to increase the "retention" of Ca and/or P by the body as a whole, the only effect of the kind which has been demonstrated for parathormone is, on the contrary, a *loss* of Ca to the body as a whole owing to the increased urinary excretion. Quite consistently, the literature will be found to indicate always the same distinctive features for parathyroid action, no matter whether the data are derived from instances of hyperparathyroidism, from parathyroidectomy or insufficiency, or from parathormone administration—viz., resorption of mineral matter from bone, raised blood calcium and increased Ca excretion by kidney, with resulting loss of Ca to the body. In short, it seems unwarranted to suppose that vitamin D acts solely by stimulating the parathyroid until evidence can be produced to show that parathormone can bring about the increased net absorption so characteristic of vitamin D.**

FIG. 4.



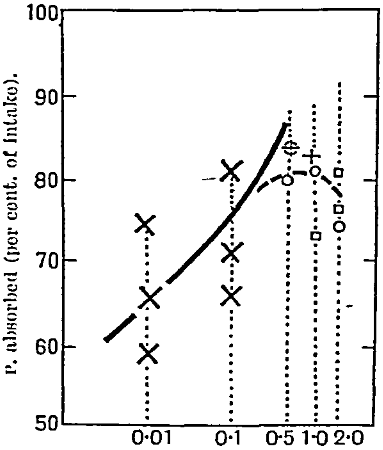
Irradiated ergosterol fed (mg. per rat per day).

Increasing net absorption of Ca with increasing intake of vitamin D (up to 5000 times the minimum effective dose). Circles and curve represent mean values. (From Brown and Shohl's figures.[16a])

Further experiments on these questions are still in progress in this laboratory, including more especially an examination of the effects of relatively small doses of parathormone in comparison with vitamin D upon normal and rachitic animals of various species. The results thus far are in keeping with the conclusions just given. It must be borne in mind that most past work on parathyroid function has been carried out on adult animals, sometimes on Ca-free diets, and principally with very large overdoses of the hormone. The conditions therefore have not been comparable with those employed in investigations on vitamin D action. and accordingly the influence of smaller doses of parathormone, and upon growing and vitamin-deficient animals, is now being examined in detail.

If we accept as correct the view of parathormone action outlined above, we need have no difficulty in accounting for the various observations which have been taken by other authors to indicate that vitamin D stimulates the parathyroid. Since, as we suppose, vitamin D and the parathyroid hormone both tend to raise the blood Ca, although in different ways, it follows that they will appear to augment each other, and hence any excess or deficiency of the one will influence the effect of an excess or deficiency of the other. But it is surely fallacious to argue that such evidence provides direct proof of an interaction between the two. Again it has been shown that parathormone injections have a more pronounced effect when large amounts of calcium are fed simultaneously; but the explanation here, it seems clear, is simply that the ingestion of extra calcium in the diet always tends to raise the blood figure (at least temporarily), so that the separate action of parathormone in

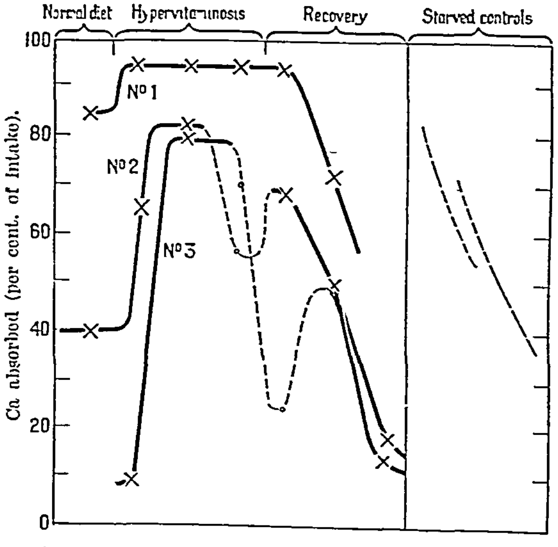
FIG. 5.



Irradiated ergosterol (mg. per rat per day).

Increasing net absorption of P with increasing excess of vitamin D complicated at the maximal levels of excess by the severe illness produced, which gives rise to loss of appetite and final failure in gut function (dotted line) (+, o, □, = cases showing loss of appetite, in increasing order of severity). (Harris and Innes[2] calculated from data of Brown and Shohl).

FIG. 6.



Net absorption of Ca measured during the course of a hypervitaminosis experiment on rats; showing the sharp rise in absorption as soon as the vitamin excess is first administered and great drop in absorption when the excess is discontinued. A secondary effect is seen in the case of rats Nos. 2 and 3 which had become gravely ill in the later stages of the hypervitaminosis, with loss of appetite and failure in gut absorption (dotted lines). A similar failure in absorption is seen in controls partly starved on a normal diet (on right) (from Watchorn's data).

** Our theory leads to the deduction that if parathormone excess induces hypercalcæmia by withdrawal of mineral from the bony reserves, this same hypercalcæmia should in turn tend to promote calcification in those regions of the bone which are more abundantly provided with phosphatase. This is in keeping with the observation that osteoid tissue may be well calcified in hyperparathyroidism.

the same direction is bound to be intensified; it would be illogical to suppose (as has been done) that this experimental result proves that parathormone increases the utilisation of food calcium.

We have mentioned above that very large doses of vitamin D tend to cause an undue density of calcification of the spongiosa in newly forming bone, while when maximal toxic doses are reached, more especially with diets not too rich in calcium, secondary resorptive changes in the over-calcified bone appear, accompanying the general growth failure, the loss of appetite, and the breakdown of gut function, &c. This secondary effect upon the bone clearly bears some resemblance to parathormone action, and a possible explanation is that the over-calcification in the bone calls for the appropriate compensating action on the part of the hormone. Taylor, Weld, Branion, and Kay,[28] who have recently independently drawn attention to the existence of resorptive bone changes in hypervitaminosis, consider, however, that it is more probable that the vitamin D is acting directly upon the gland. In support of their view they bring forward the interesting point that the relative susceptibility of different species to parathormone varies in the same manner as the ease with which they become poisoned by overdoses of vitamin D. However, before one can accept definitely the view that the action of vitamin D excess is due purely to increased parathyroid action, it will be necessary to explain certain suggestive differences between the lesions in the bone in hypervitaminosis and hyperparathyroidism. And again the occurrence, in common, of such abnormalities as calcareous deposits in soft tissues and high urinary calcium, which is also used as an argument for the supposed identity of hyperparathyroidism and hypervitaminosis,[28] could be accounted for as readily at least, we would suggest, by regarding them as a necessary feature of the hypercalcæmia per se, brought on independently by the two disorders.

REMARKS ON THE CLINICAL USE OF PARATHORMONE.

In infantile (nutritional) tetany, osteomalacia, and juvenile rickets, as well as in rickets proper, the fundamental underlying error is the inadequate net absorption of Ca and/or P, resulting in an inadequate retention of Ca and/or P by the body as a whole. The logical therapeutic or prophylactic measure is the administration of vitamin D to correct that error. It may be conceded that as an emergency measure in tetany the use of parathormone is admissible, to bring about a rapid cure of the hypocalcæmia; but its continued use, in any of the above-mentioned conditions at least, is, we wish to suggest, to be deprecated, since it tends merely to aggravate the underlying error by diminishing still further the inadequate retention of calcium and withdrawing still more mineral from the impoverished bone. That parathormone has proved invaluable after parathyroidectomy of course needs no emphasising, but unfortunately there appears to be a tendency in some quarters to prescribe it, rather than vitamin D, whenever a calcium deficiency is suspected, and in fact certain parathyroid preparations are still advocated for rickets, nutritional tetany, and "disorders of calcium metabolism" generally.††

Clinical Hypervitaminosis.

The value of irradiated ergosterol has been so fully demonstrated in clinical practice that one wishes to say nothing that might have the altogether undesired effect of discouraging its use. According to the records of a host of observers in all parts of the world—e.g., Wilkes,[30] May,[31] J. H. Hess,[32] and Alfred Hess,[33] and their respective co-workers in America, Aiden,[34] Cowell,[35] and others in England, Wiskott,[36] Aengenendt,[37] and many others in Germany, Schippers[38] in Holland, &c.—irradiated ergosterol has proved itself literally an infallible specific in the prevention or cure of rickets, if given in adequate doses. A main advantage is that it can readily be administered at much higher levels of vitamin D activity than is possible with cod-liver oil; it is well known that the latter may occasionally prove barely adequate for complete protection, particularly so with twins and premature infants. The practical significance of these considerations is seen to be very great; one has only to recall that, according to recent official *statistics,[39] close on 87 per cent. of London* elementary school-children gave evidence of having had "some degree of rickets," and that to-day "no child need have rickets." We wish then only to draw attention to the point that the human "optimum therapeutic dose" appears to be not far removed from the toxic overdose, and therefore that it is advisable to adhere closely to the correct dosage. We have been subject to some misquotation in this connexion. It is correct to say that we found the toxic overdose for the ra to be no less than 100,000 times the minimal effectiv dose, but from the outset we made it clear that th toxic overdose varied in different species, being fo the human, according to the clinical evidence then available, not far removed from the optimal thera peutic dose (not the same, be it noted also, as th minimal dose).[40 41] We suggested that our experi mental results "should not in any way discourage th rational use of the properly standardised material a the ascertainable correct physiological level," but w by no means excluded the possibility of hyper vitaminosis in humans if such precautions were no taken, and indeed we emphasised the necessity fo further standardisation.[42 40] In a later publicatio we have drawn attention to more recent clinica literature which we believe definitely indicates tha the ill-effects produced in man by overdoses o irradiated ergosterol correspond in detail with thos seen in experimental animals. The clinical instanc in question are given below to illustrate (1) th proximity of optimal dose to toxic overdose, an (2) the identity of the clinical symptoms of exce with those produced experimentally in hype vitaminosis.

A satisfactory prophylactic dose, judging from th clinical data of György,[43] Hess, Lewis, and Rivkin, Sobel and Claman,[45] and others is 0·5 mg. of irrad ated ergosterol, or more precisely expressed abou 5000 units of vitamin D (equivalent to about seve teaspoonfuls of cod-liver oil). It is probable tha the dosage at first recommended tends to be on th low side: thus Alfred Hess advocated a standar dose of 10 drops per day of "100 D"‡‡ for the fir year of life, but later it was found advisable t increase the dose to about 20 or even 30 drops.[32] At the higher level no single case of rickets appeare (see Table).

For curative treatment J. H. Hess,[32] after con siderable clinical experience, advocated a dosage o

---

†† A clinical trial of parathyroid extracts in six cases of rickets, two of them with tetany, by Hong and his collaborators,[29] resulted in the rather unsatisfying conclusion that "the reaction of individual patients . . . varies tremendously" and that "the influence of the extracts on the balance of calcium was not found to be uniformly unfavourable." An examination of their figures for the fæcal calcium, however, lends support to the contention that parathormone has either an adverse or else negligible effect on the net absorption.

‡‡ Official American preparation with 100 times the ant. rachitic activity of "good cod-liver oil."

0 to 15 drops per day of 100 D for mild rickets and 0 drops for severe rickets; no ill-effects suggestive of overdose were seen after 6 to 8 months' administration at this and higher levels. (Hypervitaminosis seems less liable to result in therapeutic than prophylactic treatment.) György, of Heidelberg, at first recommended 2 to 3 mg. of irradiated ergosterol for severe cases of rickets; later, after further clinical experience, the dose was reduced to 1 mg. per day (György [42]). Sobel and Claman [43] suggest as optimal therapeutic doses: for children under 1 year of age, 1 to 2 mg. per day, in divided doses; for children over 1 year, 3 to 4 mg. Hess, Lewis, and Rivkin [44] found 1 mg. to be the adequate dose for an average case of rickets.

Table showing Relative Value of Various Antirachitic Prophylactic Measures, from Data of J. H. Hess, Poncher, Dale, and Klein.[32]

No. of infants.	Treatment.	Result after 5–8 months' treatment.	
		Cases of severe rickets.	Cases of "slight" rickets.
63	Viosterol 100 D, 10–20 drops per day	0	0
6	Viosterol 100 D, 10 drops or less per day..	0	6
44	Cod-liver oil, 1–3 teaspoons to 2 tablespoons per day.. ..	2	4
34	Controls, no treatment ..	9	10

Giving 2·5 to 5 mg. of irradiated ergosterol the last-mentioned authors encountered what appear to constitute the first recorded cases of clinical hypervitaminosis. The abnormalities observed included: three cases of hyperphosphatæmia (without apparent ill-effects), several cases of excessively calcified bone and of hypercalcæmia, two of the latter manifesting untoward clinical disturbances. György at Heidelberg relates a similar experience using doses around 4 mg. of irradiated ergosterol. A single case of calcification in the kidney with fatal termination, apparently due to hypervitaminosis, was seen by Putscher (1929 [47]); three instances of renal lesions after vigantol (Klaussner-Crohein, 1930 [48]); renal damage after three teaspoonfuls of vigantol taken in error during one day (Tu-Tungi, 1931 [49]); raised blood Ca or P in normal children or adults given 5 to 10 mg. (Hughes et al., 1929 [50]; Lasch. 1928 [51]; Ghirardi, 1929 [52]); and loss of Ca by way of the urine in normal children given very large overdoses (Hottinger, 1929 [53]). A recent fatal case is that recorded by Thatcher [54] at Edinburgh, who described typical calcareous deposits in the kidney.

In the foregoing clinical instances we see all the most characteristic signs of experimental hypervitaminosis, including the hypercalcæmia and/or hyperphosphatæmia, the overcalcified bone, the excessive urinary excretion of Ca and/or P (with renal damage), first described in this laboratory. In conclusion one may note, perhaps not without relief, that (as also in experimental animals) the ill-effects disappear rapidly, leaving no permanent injury if the excess of irradiated ergosterol is discontinued with no undue delay. From a practical standpoint hypervitaminosis D is almost impossible of production on natural foodstuffs, all of which in comparison are relatively inert. (As many as 14 teaspoonfuls of cod-liver oil per infant per day would be needed to give the same approximate antirachitic potency as the therapeutic optimum of 1 mg. of irradiated ergosterol.) Cod-liver oil in very large excess can, it is true, give rise in experimental animals to certain ill-effects of its own, which are quite distinct from those of hypervitaminosis D (Harris and Moore,[42] [55] Norris and Church [56]); and it has been suggested that infants can suffer in the same way (Agduhr [57]). Recently we have discovered that if cod-liver oil be oxidised by aeration such toxicity is vastly increased (Harris [58]).

Summary.

1. Investigations on hypervitaminosis have substantiated the theory that the characteristic mode of action of vitamin D is to permit an increased "net absorption"[‖] of Ca and/or phosphate from the gut, tending to raise the level of the blood calcium and/or phosphate: the latter rise automatically brings about increased calcification in sites provided with the "bone," or "calcifying" enzyme, phosphatase. This action is apparent whether the vitamin is fed in suboptimal amounts, in doses approaching the optimum, or in moderate excess. Hypervitaminosis thus stands in logical contrast with rickets (hypo- or a-vitaminosis). In the latter there is deficient net absorption of calcium and/or phosphate, hence hypocalcæmia and/or hypophosphatæmia, and resulting insufficient calcification; while in hypervitaminosis there is a potential increase in net absorption, hypercalcæmia and/or hyperphosphatæmia, and excessive calcification in sites such as the growing end of the bone, in teeth, &c., and also in certain soft tissues such as the kidney and aorta, which are also richly provided with the "bone" enzyme.

2. The foregoing theory of vitamin D action permits a ready explanation of the following: the variation between species, in measures needed to induce rickets—e.g., rat compared with dog or human: the ætiology of experimental nutritional tetany compared with low-phosphate rickets; the influence in hyper- and hypo-vitaminosis of the Ca intake, Ca—P ratio, &c.

3. Like vitamin D the parathyroid hormone can also raise the level of the blood Ca, but the available evidence suggests that it does so solely by draining the mineral matter from the bone, and there are no records of increased net absorption from the gut. Until evidence is offered of the latter characteristic action, the theory cannot be accepted that vitamin D acts normally by simple stimulation of the parathyroid. Parathormone has been shown by past workers to bring about a loss of calcium to the body owing to the increased urinary excretion; the vitamin, on the other hand, in amounts up to moderate overdoses, tends to augment "retention" (the potential increase in net absorption exceeding any increase in urinary excretion). It is suggested that such symptoms as the increased urinary excretion and calcareous deposition common to both hypervitaminosis and hyperparathyroidism do not necessarily indicate stimulation of parathyroids by vitamin D excess, but may be attributed to the hypercalcæmia and/or hyperphosphatæmia to which both conditions independently give rise.

4. The indiscriminate use of parathormone clinically for cases of suspected calcium deficiency is to be deprecated, most definitely in such conditions as

---

[‖] An increase in "net absorption" implies an *increase* in the gross amount absorbed from the gut or a *decrease* in the amount excreted back into the gut—i.e., of material previously absorbed.

infantile tetany, osteomalacia, late rickets, &c.; for although it will succeed in raising a low blood calcium, it merely aggravates the underlying metabolic error (inadequate retention of Ca and/or P), causing loss of minerals to the body, and still further depleting the already impoverished bones. Vitamin D, on the contrary, rectifies hypocalcæmia (or hypophosphatæmia) by ensuring an adequate utilisation of the food Ca (and/or P).

5. Complicating secondary effects occur in experimental hypervitaminosis when the maximal levels of toxicity are reached and have led to some misunderstanding. Loss of appetite and failure in gut function results in little calcium being absorbed (the absorption fails equally in partially starved controls having no excess of vitamin D), and since urinary excretion remains high the retention by the animal as a whole now tends to drop. Again, if maximal toxic doses of vitamin D are given, under these circumstances and particularly if the calcium intake is not correspondingly increased, secondary resorptive changes are seen in the bones, which can therefore provide an alternative source of some of the extra Ca drawn into the blood.

6. The ill-effects in hypervitaminosis are the same in man as in experimental animals. Clinical experience shows that for the human the toxic overdose of irradiated ergosterol is not far removed from the optimal (not "minimal") curative dose. The correct dosage should therefore be strictly adhered to.

THE TREATMENT OF

INFECTIONS OF THE URINARY TRACT BY A KETOGENIC DIET.

BY PROF. HUGH CABOT, C.M.G., M.D., F.A.C.S.,
CONSULTING SURGEON TO THE MAYO CLINIC,
ROCHESTER, MINN.

IN October, 1931, Dr. H. F. Helmholz and Dr. A. L. Clark presented to the staff of the Mayo Clinic the results of work which they had been doing quite independently on the effects of a ketogenic diet upon infections of the urinary tract.[1] Dr. Helmholz, working entirely with children, had been attracted to this study by the observation that the urine of children under treatment by a ketogenic diet for epilepsy was extraordinarily resistant to putrefaction. Dr. Clark undertook his investigations on account of the observations made by W. M. Clark[2] in 1915, which appeared to show that colon bacilli are inhibited from growing in urine at a pH of 4·6 to 5·0 on the acid side, and 9·2 to 9·6 on the alkaline side. It is interesting to note that each of these two observers carried out his experiments without the knowledge that the other was also working on the problem. Dr. Helmholz had previously studied the effect of acidification of the urine by means of ammonium and calcium chloride, producing a reaction with a pH of about 5·0, and had observed that this measure would accomplish the sterilisation of the urine in some cases but not in others. His experience, in common with that of many other observers, had been to the effect that while it was generally possible to sterilise the urine of children by the use of drugs in the absence of obstructive lesions, in the presence of such lesions—for instance, various types of hydronephrosis—sterilisation could not be obtained. He had in his care a child of 8 with a chronic infection of the urinary tract and marked hydronephrosis on the left side; he found that it was impossible to sterilise the urine by the use of various drugs, including ammonium chloride. When a ketogenic diet, producing an acidity of 5·5, was given, sterilisation of the urine was obtained. He also observed on this patient that after the diet had been discontinued and the urine returned to an acidity of only 6·4, it nevertheless remained sterile.

---

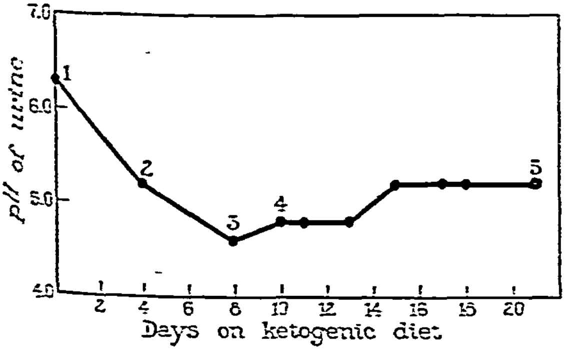
[1] Proc. Staff Meetings, Mayo Clinic, 1931, vi., 605, 609.
[2] Jour. Biol. Chem., 1915, xxii., 87, 98.

His next trial of the method was made upon a child of 9, who was known to have had a chronic urinary tract infection for three years, accompanied by recurrent attacks of fever and renal pain. Examination showed an albuminuria of grade 2 and a pyuria of grade 4 (these grades being on a scale of 4). Cultures from the bladder and ureters showed innumerable colonies of *Streptococcus hæmolyticus*. Further examination disclosed a diffused cystitis, bilateral pyelonephritis, bilateral hydronephrosis and hydro-ureter, with probable duplication of the ureter on the left side. This patient reacted in a manner similar to that of the other: by treatment with drugs it was not possible to sterilise the urine, but on the third day after the commencement of a ketogenic diet, with an acidity of 5·8, the urine was sterile. These observations have been followed by others giving similar results.

Dr. Clark, on the other hand, was working only with adult patients, and had been striving with the usual unsatisfactory results to sterilise the urine by the use of drugs. His first observation was made upon a man of 54 whom he first observed in May, 1931.

For the previous 18 months the patient had been suffering from burning on urination, with frequency, urgency, perineal discomfort, and serious nocturia. Careful examination revealed the presence of bilateral pyelonephritis and chronic prostatitis. There was no obstruction at the bladder neck. Careful treatment by the usual methods of bladder irrigation, prostatic massage, and the administration of urinary antiseptics failed to improve the situation. Urine cultures showed many colon bacilli. The urine was cloudy to hazy, and contained shreds. On July 21st he was put upon a quantitative ketogenic diet. On July 25th the urine was clear and showed an acidity of 5·2. The symptoms were also markedly improved. On July 29th both glasses of urine remained clear: the acidity was 4·5 and the urine was sterile to culture. By this time irritation, frequency, and nocturia had disappeared. Fig. 1 shows the reaction of the urine in this case under treatment. On August 10th the patient was dismissed from the clinic and advised to continue a qualitative ketogenic diet at home. On August 24th he was re-examined: the urine was found to have remained clear and sterile, and showed a reaction of 4·8.

FIG. 1.



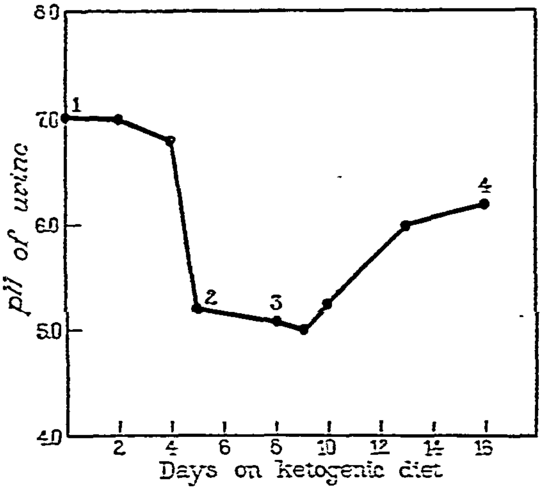
Case 1.—Features corresponding with the numerals on the graph are as follows: 1, both glasses of urine in the two glass test cloudy, urination at night three to four times, frequency and urgency, many bacilli in sediment; 2, symptoms improved, glass 1 slight haze, glass 2 clear; 3, no frequency, no nocturia, occasional bacilli in sediment, urine clear; 4 and 5 no growth on culture.

A second case was that of a man of 63, who came under observation on August 11th, 1931.

In the previous May he had developed serious nocturia, with urgency and perineal discomfort. From May 1st to August 1st various drugs and methods of local treatment had been tried but without benefit. The urine showed a very free growth of colon bacilli. On August 24th the patient was given a ketogenic diet; the reaction of the urine is shown in Fig. 2. On August 29th the urine was clear; cultures were free from colon bacilli but yielded a few colonies of *Aerobacter aerogenes*. On Sept. 1st the urine was entirely sterile, and remained so during the next ten days.

These cases under the care of Helmholz and Clark appeared to point to a very important effect produced upon urinary tract infections through increasing the acidity of the urine by a ketogenic diet. They served to stimulate our interest in this method of treatment, and have been followed by a number of further observations with similar results. It will be noted that the effect upon the bacteria in the urine is not produced simply by the acidity; neither Helmholz nor Clark, working respectively with children and with adults and producing an acidity of about 5 by means of drugs, could sterilise the urine. On the other hand, an acidity of even lesser amount produced by a ketogenic diet was promptly effective. It appears, therefore, to follow that the acidity produced by diet has a very much more powerful sterilising effect than that produced by drugs. There is at least a strong suggestion that a ketogenic diet, operating not only through the urine, but—quite obviously—through the blood stream, will produce an effect upon the cells themselves, and will act at a much deeper level than where dependence is placed upon the contact of an acid urine with the superficial tissues.

FIG. 2.



Case 2.—Features corresponding with the numerals on the graph are as follows: 1, urine cloudy, urination at night two to three times, frequency, urgency, dysuria; 2, urine clear, Escherichia coli in culture, symptoms greatly relieved; 3, no growth on culture; and 4, still no growth on culture although pH was up to 6·2, no nocturia, frequency, or urgency.

It is practically interesting to consider what apparently objectionable effects this treatment may have. We have all in the past been familiar with the serious conditions found in children in the presence of marked ketosis, resulting either from starvation alone or from starvation associated with disease. There is at least a strong suggestion that the ketosis intentionally produced by diet is in some respects different from that seen in disease, and that the classical picture of ketosis does not result; further, that the bodies producing this reaction in the urine may not be precisely similar when liberated by these two different methods. Consequently, much further work in the chemistry of the urine under these conditions is indicated.

infantile tetany, osteomalacia, late rickets, &c.; for although it will succeed in raising a low blood calcium, it merely aggravates the underlying metabolic error (inadequate retention of Ca and/or P), causing loss of minerals to the body, and still further depleting the already impoverished bones. Vitamin D, on the contrary, rectifies hypocalcæmia (or hypophosphatæmia) by ensuring an adequate utilisation of the food Ca (and/or P).

5. Complicating secondary effects occur in experimental hypervitaminosis when the maximal levels of toxicity are reached and have led to some misunderstanding. Loss of appetite and failure in gut function results in little calcium being absorbed (the absorption fails equally in partially starved controls having no excess of vitamin D), and since urinary excretion remains high the retention by the animal as a whole now tends to drop. Again, if maximal toxic doses of vitamin D are given, under these circumstances and particularly if the calcium intake is not correspondingly increased, secondary resorptive changes are seen in the bones, which can therefore provide an alternative source of some of the extra Ca drawn into the blood.

6. The ill-effects in hypervitaminosis are the same in man as in experimental animals. Clinical experience shows that for the human the toxic overdose of irradiated ergosterol is not far removed from the optimal (not "minimal") curative dose. The correct dosage should therefore be strictly adhered to.

THE TREATMENT OF

INFECTIONS OF THE URINARY TRACT BY A KETOGENIC DIET.

BY PROF. HUGH CABOT, C.M.G., M.D., F.A.C.S.,
CONSULTING SURGEON TO THE MAYO CLINIC,
ROCHESTER, MINN.

IN October, 1931, Dr. H. F. Helmholz and Dr. A. L. Clark presented to the staff of the Mayo Clinic the results of work which they had been doing quite independently on the effects of a ketogenic diet upon infections of the urinary tract.[1] Dr. Helmholz, working entirely with children, had been attracted to this study by the observation that the urine of children under treatment by a ketogenic diet for epilepsy was extraordinarily resistant to putrefaction. Dr. Clark undertook his investigations on account of the observations made by W. M. Clark[2] in 1915, which appeared to show that colon bacilli are inhibited from growing in urine at a pH of 4·6 to 5·0 on the acid side, and 9·2 to 9·6 on the alkaline side. It is interesting to note that each of these two observers carried out his experiments without the knowledge that the other was also working on the problem. Dr. Helmholz had previously studied the effect of acidification of the urine by means of ammonium and calcium chloride, producing a reaction with a pH of about 5·0, and had observed that this measure would accomplish the sterilisation of the urine in some cases but not in others. His experience, in common with that of many other observers, had been to the effect that while it was generally possible to sterilise the urine of children by the use of drugs in the absence of obstructive lesions, in the presence of such lesions—for instance, various types of hydronephrosis—sterilisation could not be obtained. He had in his care a child of 8 with a chronic infection of the urinary tract and marked hydronephrosis on the left side; he found that it was impossible to sterilise the urine by the use of various drugs, including ammonium chloride. When a ketogenic diet, producing an acidity of 5·5, was given, sterilisation of the urine was obtained. He also observed on this patient that after the diet had been discontinued and the urine returned to an acidity of only 6·4, it nevertheless remained sterile.

140, and his respiration-rate 25 per minute. Examination of the central nervous system revealed bilateral ptosis, but no squint or other affection of the cranial nerves. Neck rigidity was fairly marked and Kernig's sign was positive on both sides of the body. The knee-jerks were both brisk and the plantar responses doubtfully flexor in type. No abnormalities were present in the chest or abdomen. The urine was normal. The ear-drums were normal on both sides

Lumbar puncture revealed turbid cerebro-spinal fluid under increased pressure. On analysis it showed: cells, 1000 per c.mm., 75 per cent. polymorphonuclear in type; chlorides, 672 mg. per cent.; protein present in large quantity; sugar much reduced in quantity (the fluid had, however, been standing for 12 hours). On culture a Gram-negative bacillus was isolated.

The child became more and more comatose and emaciation became marked. The rigidity of the neck and limbs steadily increased until death, which took place nine days after admission. During this time his temperature swung from 97° to 99·6° F., rising above this only for a few hours before death. The pulse-rate remained constantly between 140 and 160 until the day before death, when it dropped to 108; on the day of decease it rose rapidly and became uncountable. The respiration-rate was 30–40 during the whole period. The bowels were constipated and enemata were required for their relief on occasion.

Lumbar puncture was performed daily. For the first six days after admission the fluid was turbid and under increased pressure. From this time until death it became so thick as to flow through the needle only in small amount and very slowly. Four days before death he developed a severe conjunctivitis, and in the evening he had a convulsion. From this time until his end he became more rigid and opisthotonic. The cerebro-spinal fluid was by now very thick and obtained in too small quantity to permit analysis. He died on July 5th, nine days after admission. No autopsy was allowed.

CASE 2.—A boy of 8, sent in by Dr. C. W. Coulter, was admitted on July 4th, 1931, with a history that two days before he had been seized with severe headache and vomiting. That night he had been delirious, and on the following day the headache and vomiting had continued. He was again delirious at night, but the following day, the day of his admission, he had stopped vomiting, though the headache had continued. He had also developed some pain in the right side. His bowels had been opened each day with a normal result.

On admission he was flushed, feverish, and irritable, the temperature was 102·8° F., the pulse-rate 120, and the respiration-rate 40. The tongue was furred, and there was slight stiffness of the neck and legs, but no other abnormality of the central nervous system. No abnormality was found in the cardiovascular system or abdomen, but there was a slight bronchitis. No rash was present; the ear-drums were both normal. Lumbar puncture was performed, the fluid obtained being clear and under increased pressure. The urine was normal. A provisional diagnosis of typhoid fever was made and a blood culture immediately performed, which yielded a Gram-negative bacillus.

On the day after admission his condition was unchanged; he had been slightly delirious over-night, but was now rational. The spleen was just palpable; it had not been felt on admission. His temperature had dropped to 100° F., and his pulse-rate to 90. On the following day he had improved markedly. His temperature was normal, his pulse-rate 88, and, beyond a slight cough, he was comfortable. From this point his recovery was rapid; the spleen was not again felt, the cough improved, and the last signs to go were the slight rigidity of the neck and legs. His bowels were very constipated, and for over a fortnight he required enemata to obtain an evacuation. His pulse-rate and temperature remained normal, and he was discharged cured on July 24th, 20 days after admission. His treatment for the first four days, until the diagnosis was finally established, was that usually prescribed for typhoid fever. After this a light varied diet was given, no other therapeutic measures being employed.

PATHOLOGY.

The cytological examination of the cerebro-spinal fluid from Case 1 showed a very high content of polymorphonuclear cells, indicating a septic type of meningitis. In the first specimen of cerebro-spinal fluid withdrawn dried smears revealed a Gram-negative bacillus of coliform appearance present in small numbers. Some forms were in pairs, but morphologically tended to be diplobacillary rather than diplococcal. Cultures on blood and trypsin-agar were sterile at this stage. Much protein was present in the form of globulin and albumin. The chloride content was very slightly reduced—viz., 672 mg. per 100 c.cm. On June 29th the sugar content was reduced to zero. The accompanying table summarises the changes found in the cerebro-spinal fluid:—

Date in 1931.	Cells.	Polymorphs (per cent.).	Dried smears.	Chlorides (mg. per cent.).	Sugar.	Albumin.	Globulin.	Cultures.
June 27	1000	75	Few G.-n. bac.	672	..	+++	+++	Sterile.
29	..	..	..	622	0	++	+	—
July 1	1330	70	Many G.-n. bac.	669	17	++	+	Blood-agar: sterile. Broth: G.-n. bacillus.
2	..	..	..	657	11	++	+	Blood-agar: coliform colonies. Serum water: G.-n. bacillus.
3	700	90	G.-n. bac.	..	..	..	..	

G.-n. bac. = Gram-negative bacilli.

Subculture of colonies on blood-agar, which at an early stage were more or less "pin-point" in appearance, yielded on MacConkey's medium a pure non-lactose fermenting growth. The fermentation reactions of this organism, which was a Gram-negative motile bacillus, were as follows:—

Lactose ..	Alkaline.	Milk ..	Alkaline.
Glucose ..	Acid and gas.	Gelatin ..	No liquefaction.
Mannite ..	Alkaline.	Indol ..	+
Dulcite ..	,,	Voges-Proskauer	—
Saccharose	,,		

These reactions were unchanged after 12 days, and are characteristic of Morgan's No. 1 bacillus. As agglutinating serum for Morgan's bacillus was not readily available, the organism was submitted to Prof. C. J. Lewis and Dr. Bayliss Ash, of the University of Birmingham, who were kind enough to send the following report:—

> "The organism was compared with our standard Morgan's bacillus No. 1 with regard to cultural characteristics, fermentation reactions, and agglutination against a Morgan antiserum prepared in the laboratory. This organism was agglutinated at a titre of 1–900, and it agrees in all characteristics with our stock Morgan's bacillus."

It should be noted that in this form of meningitis the chloride content was slightly, but definitely, below normal; the average content of the four estimations made was 655 mg. per 100 c.cm. Neale and Esslemont[1] found that 730 mg. was the average amount in children from whom cerebro-spinal fluid was withdrawn but who proved to be non-meningitic, while cases of tuberculous meningitis averaged 613 mg. The sugar content was very definitely diminished, and its behaviour is apparently similar to that in other cases of septic meningitis—e.g., meningococcal and pneumococcal.

In Case 2 a Gram-negative bacillus was isolated from the blood on July 4th. This gave the fermentation reaction characteristic of Morgan's No. 1 bacillus, exactly as in Case 1. The sugars were left for 12 days and showed no change. Prof. Lewis and Dr. Ash kindly tested the organism for agglutination powers and reported: "The organism agrees similarly and is agglutinated by the Morgan antiserum to a titre of 1–1200."

DETAILS OF THE DIET.

The following are details of a qualitative ketogenic diet giving approximately 2500 calories per day :—

Carbohydrate	20 grammes	Protein	70 grammes
Fat	240 grammes		

Food allowance for 1 day.

Butter, 10 squares	$^{1}/_{5}$ lb.
Cream, heavy-whipping	$^{1}/_{2}$ pint
Bacon	4 strips
Eggs	2
Meat	4 oz.

Soya bean muffins, 3. 5 per cent. vegetables, 4 servings; 2 cups, such as spinach, asparagus, tomato, celery, lettuce, and cucumber.

Tea and coffee, sweetened with saccharin.

This diet is probably one which for most patients will be disagreeable, and which for some patients will be impossible to enforce for a period sufficiently long to produce results. The work of Helmholz suggests that the diet will produce a more prompt effect in children than in adults. In the latter group at least seven days was required in 15 of Clark's patients to produce sterility, while in one case as much as 35 days were required to sterilise the urine completely. In yet another case it was impossible to produce an acidity lower than 6, and no sterilising effect was obtained. In three more cases the diet could not be tolerated. There thus appears to be an important personal factor, perhaps more important in the adult than in the child, but it is clear that many further observations upon this point will be required.

CONCLUSIONS.

Clark,[3] in a personal communication in March, 1932, draws the following conclusions :—

1. "The general condition of the patient must be such that he can endure the alteration in his diet. A patient who is able to take a moderate amount of exercise is a far more satisfactory subject for this type of treatment that one who is necessarily confined to bed.

2. "Coöperation of the patient is absolutely necessary. In Cases 2 and 6 the patients were not coöperative, and the results obtained, as judged by the pH of the urine, were correspondingly disappointing.

3. "The patient must be able to digest and assimilate fats. This was very clearly demonstrated in Case 15; the patient apparently was unable to prepare the ingested fats for assimilation. He had undergone resection of the stomach, but whether this fact is relevant to his inability to rid himself of bacilluria cannot be stated.

4. "The normal intake of fluid should be maintained. Increase in the intake of fluids may cause undesirable dilution of ketogenic products.

5. "If the infection is in the upper part of the urinary tract, treatment must be continued for a longer time than if the infection is in the bladder.

6. "The ketogenic diet tends to entail constipation and gastro-intestinal upsets, but a dietitian can forestall these effects."

This brief survey of the work of Helmholz and Clark appears to me to warrant the following tentative conclusions : (*a*) Acidity produced by a ketogenic diet is more effective than an equal acidity produced by drugs. (*b*) Acidity does not cause bladder irritation, as has been assumed in the past; on the contrary, irritation existing in the presence of urinary infection will be relieved by increasing the acidity of the urine at least to the extent that the infection is favourably influenced. (*c*) This method opens up an interesting field for further investigation, and may importantly affect the results of operations upon the urinary tract undertaken in the presence of previous chronic infection. Thus, we have hesitated to operate upon patients with infected hydronephrosis, and when we have done so some of them have shown violent increase of infection with serious consequences. If, as a result of this method of treatment, the infection in these kidneys can be controlled before operation, *then the result of the operation, both as regards risk* and permanency, is likely to be very much improved.

An interesting speculation in which one might indulge is on the effect of such treatment in preparing patients with prostatic obstruction for operation. Undoubtedly the largest single factor in the mortality of such operations, and also in the morbidity which follows successful intervention, is our inability to deal satisfactorily with existing infection. If it should prove possible to diminish or to abolish infection before operation, a very important improvement in our results would accrue. It is just conceivable that we might be able to produce before operation a certain protective mechanism in the tissues themselves which would enable them to withstand the increased chance of infection, whether of the lower or of the upper urinary tract, during the early days after operation. It is precisely here that we have in the past been most helpless, and therefore it is here that we need help.

The method appears to me a very important and interesting one which should be widely investigated, so that the suggestions made on the relatively small series of cases treated by Helmholz and Clark may be affirmed or denied. It is not impossible that a ketogenic diet may be found to act differently on peoples who normally live on widely different diets. Should this prove true, the results of the method might be importantly different in different parts of the world, and the method might thus prove more valuable in certain countries than in others.

MENINGITIS AND SEPTICÆMIA

DUE TO MORGAN'S NO. 1 BACILLUS.

By Robert Gittins, M.D. Birm., M.R.C.P. Lond., D.T.M. & H.,
PATHOLOGIST, CHILDREN'S HOSPITAL, BIRMINGHAM;
AND
J. C. Hawksley, M.D., M.R.C.P. Lond.,
LATE RESIDENT MEDICAL OFFICER TO THE HOSPITAL.

Infections of the blood with Morgan's No. 1 bacillus are rare, and infection of the meninges with this organism must be extremely uncommon, since we have not been able to find a reported case. The presence at the same time of two cases in the Birmingham Children's Hospital—one of septicæmia and the other of meningitis—presented an opportunity for their investigation and comparison. These children came from different places, some miles apart, and had at no time been exposed in any way to a common source of infection.

Case 1.—A boy, aged 1½ years, sent in by Dr. F. M. Rowland, of Lichfield, was admitted on June 26th, 1931. He had been well until the 22nd, when he became restless. The following day he was drowsy and irritable; he also developed dirty habits, from which he had previously been free. During the day of June 26th he became worse and cried out without reason.

On admission he was drowsy and very ill. He was flushed, his temperature was 100° F., his pulse-rate was eble the rate of flow, presumably because the orifice as occluded by some adjacent tissue.

---

[3] Clark, A. L.: Personal communication, March, 1932.

APPARATUS AND TECHNIQUE.

There are various types of manometer on the arket and probably the best are the simplest which onsist of a glass tube of narrow bore, graduated n centimetres, which can readily be attached to the eedle after withdrawal of the stilette.

The one I use is readily made from a piece of thermometer ubing, some 50 cm. in length, with a bore of 0·5 to 1 mm.; his is bent at a right angle 3 cm. from one end, in the flame f a burner, care being taken by blowing through it meanhile that the lumen does not become occluded; the ent end may either be fused into a metal nozzle that will t the lumbar puncture needle, or else attached to the nozzle y a short length of rubber pressure tubing. In graduating uch a manometer it is necessary to make a correction for apillary attraction since zero does not coincide with the evel of the needle; the lower end of the manometer is laced in a dish containing cerebro-spinal fluid (preferably mixture from several patients) and, with the nozzle ust below the level of the fluid, the latter will be seen to ise up the tube a distance of as much as 5 cm., the height arying according to the diameter of the tube; when the osition of the meniscus is definitely ascertained this point s marked as zero, with a diamond pencil, and the tube raduated upwards from here.

Such a manometer may conveniently be sterilised before se by attaching a rubber teat to the upper end, immersing he lower end in a dish of spirit and drawing the spirit up he tube by compressing the teat; finally the spirit is xpelled in like manner until it is dry.

For the purpose of manometric readings it is necessary that lumbar puncture be performed with the patient lying on his side; in the sitting position, as used by Raynaud, the pressure will be influenced by the length of the patient's back.

When the stilette is withdrawn from the needle and fluid begins to flow, the manometer is immediately attached; it is then essential that the patient's head should be on the same level as his spine and lying in a comfortable position; the legs should be extended slightly and the patient directed to lie perfectly still without straining. This is one of the most important points of the whole procedure and undoubtedly constitutes the largest source of error. One finds in almost every case that the fluid rises to a considerable height at first and only returns to its true level after the lapse of a few minutes; the fall is frequently accelerated if the patient is instructed to take a few long breaths, so as to relax the abdomen. It is well to slope the manometer a few times, thus allowing the fluid to run up nearly to the top, and observe whether it returns constantly to the same level. As a further precaution, lest the needle should be occluded, it is advisable to compress the jugular veins and so elicit the Queckenstedt phenomenon; this last provision has the added advantage of detecting spinal block or, as in one case recently seen by the writer, an unsuspected lateral sinus thrombosis. In infants or young children who cry it is quite useless to attempt to measure the pressure, and the same is true of lunatics or other persons who have to be restrained during the operation; the slightest exertion on the part of the patient is recorded by a rise in the pressure.

RESULTS OF EXAMINATION.

In the cases now to be reported the patients are all syphilitic natives of the Sudan; they include those attending local hospitals and also various native soldiers and prisoners whose bloods were found, on routine examination, to be sero-positive. This work is being done in a study of syphilis among the Sudanese, the results of which will be published at a later date. Complete examinations have now been made of 313 patients in various stages of the disease.

1. *Primary Cases*, with chancre but no secondary signs.—This group comprises 22 individuals, of whom 9 had increased cell counts (over 3 per c.mm. in Fuchs-Rosenthal's chamber) and/or a total protein of over 30 mg. per cent. (by Mestrezat's diaphanometric method). The average pressure in this group was 11 cm. of fluid and the extremes were 2 and 18; the fluid with the highest cell count (35⅓ per c.mm.) and a positive Pandy reaction had a pressure of 11 cm. of fluid.

2. *Secondary or Early Tertiary Cases*, with skin lesions.—There were 55 cases, of which 15 had positive changes in the cerebro-spinal fluid, as defined above. The average pressure was 9·9 cm. of fluid and the extremes 0 and 15. The case with zero pressure had 4⅓ cells per c.mm. and a protein content of 35 mg. per cent.; there can be no doubt as to the validity of this reading as compression of the jugular veins produced an immediate rise in the manometer tube and this fell promptly to the zero mark when pressure was released. Another patient in the group with 38⅓ cells, 50 mg. of protein, and a positive Pandy and +++ Kahn had a pressure of only 2 cm. of fluid; and one with 45 cells, 40 mg. protein and + Kahn had a pressure of 14 cm. of fluid.

3. *Tertiary Cases* with active cutaneous or visceral lesions.—There were 53 cases in this group and 23 had positive fluids. The average pressure was 10·7 cm. of fluid, with extremes of 0 and 26; the one with a pressure of 26 was a case of syphilitic carditis with extreme decompensation and ascites so that here the hypertension may well have been of purely mechanical origin. One with a pressure of 25 cm. was a man with extensive ulceration of the palate and a cerebro-spinal fluid containing 8⅓ cells and 45 mg. per cent. of protein, with + Kahn reaction. The next highest, with a pressure of 18 cm. of fluid, was a case of cirrhosis with ascites and an otherwise normal fluid. The remainder were all 16 cm. of fluid pressure, or less. A solitary case with zero pressure was a man with specific iritis whose fluid contained 40 mg. per cent. of protein and no cells in 3 c.mm. In this group, therefore, we can only cite one case, that with ulceration of the palate, as having hypertension of the cerebro-spinal fluid if we accept as our upper limit of normality a pressure of 20 cm. of fluid.

4. *Congenital Lesions.*—In only six cases in this group was it possible to take an accurate manometric reading; of these four had positive fluids. Only one, a boy with a criminal record, scarring of the tibiæ from old gummata and exaggerated tendon reflexes, had a pressure of 22 cm. of fluid; he had a protein of 45 mg. per cent. and 1⅓ cells. The remainder had pressures between 7 and 15; one, with a cell count of 168 per c.mm., protein 50 mg. per cent. Pandy +, Kahn +++ and a weak luetic Lange gold curve, had a pressure of 10 cm. of fluid.

5. *Latent Tertiary*, with no apparent lesions clinically.—Of 157 in this group 28 had positive fluids. The average pressure was 10 cm. of fluid and the extremes were 0 and 22. The one case with the pressure of 22 had Kahn + in his fluid but no other abnormality; this was the only one above 18. A patient with 424 cells, of which 4 per cent. were plasma cells and 1 per cent. polymorphonuclears, a protein of 60 mg. per cent., Pandy ++, Kahn +++ and a luetic gold curve, had a pressure of 15 cm. of fluid, and two others with 323 and 184 cells and other findings parallel had pressures of 11 and 12 cm. respectively. Two cases with zero pressure had normal fluids.

6. *Neurosyphilis and Retinitis.*—Twenty cases, with positive fluid in 13. This group had an average pressure of 11 cm. of fluid and extremes of 0 and 31. The group included the following: hemiplegia of probable syphilitic origin, 3 cases; cranial nerve palsies, 2; hemiplegic Jacksonian epilepsy, 1; choroiditis, 3; optic atrophy, 2; retrobulbar neuritis, 1; thrombosis of retinal artery, 1; transverse myelitis, 1; neuro-recurrence, with meningeal signs, 2; chronic syphilitic meningitis, 1; peripheral neuritis, 2; and one case with a history of maniacal outbursts, a positive fluid, but no sign of G.P.I. One of the neuro-recurrences had 1856 cells per c.mm., a protein content of 240 mg. per cent., positive Kahn, globulin and gold reactions, and a pressure of 31 cm. of fluid; this was the only one with a pressure over 16 cm. of fluid; the other neuro-recurrence, of lesser magnitude with 94 cells, had a pressure of 9 cm. of fluid.

DISCUSSION AND SUMMARY.

There is a lamentable lack of information in the literature about the actual degree of pressure that may be considered normal. Some of the authors whose figures are quoted at the beginning of this paper considered 20 cm. of fluid as the upper limit of normal, An anomalous feature of this case was the isolation, from the cerebro-spinal fluid on July 4th, of a Gram-negative bacillus in broth, which, on subculture on MacConkey's medium, yielded lactose-fermenting colonies. As this fluid when taken on admission showed no cytological changes suggestive of meningitis, and as the nature of the illness (later proved to be a Morgan's septicæmia) was not then appreciated, this organism of apparently coliform type was regarded as an inadvertent contamination and was not further investigated. In the light of the subsequent results of subculture of the organism from the blood, it is possible, if not probable, that an error of observation regarding the lactose-fermenting capacity of the cerebro-spinal fluid organism was made, and that this too was in fact Morgan's No. 1 bacillus. It is interesting to note that on the fifteenth day of the illness the serum did not agglutinate the Morgan's No. 1 bacillus isolated; this contrasts with typhoid infections, in which a positive Widal test may be expected any time after the seventh day. As the child recovered, no further pathological investigations were made.

DISCUSSION.

We have not been able to trace any definite record of meningitis caused by Morgan's No. 1 bacillus. Cases of septicæmia are known to occur. Dick and Williams [2] have reported on an epidemic which was attributed on rather doubtful grounds to Morgan's bacillus. One case, on which no bacteriological examination was made, developed meningitis. Symmers and Wilson [3] report three cases of meningitis due to anthrax, typhoid, and Gaertner's bacillus. The last occurred in a child 4 months old, with an onset of vomiting and diarrhœa, and later typical signs of meningitis. Twice during life and at post-mortem examination they cultivated from the cerebro-spinal fluid an organism proving, by fermentation and agglutination absorption experiments, to be the bacillus of Gaertner. The intestine showed no inflammation; the Peyer's patches were not swollen; the brain showed a fibrinous exudate at the base. Kortenhaus records septicæmia, caused by Morgan's bacillus, and other cases of septicæmia with meningitis by allied organisms as the ætiological agents have been reported—e.g., by Friedländer's bacillus,[4] by *B. acid. lact.* (in the new-born),[5] by the colon bacillus (Navarro [6] and Bardisian [7]), and by *B. paratyphosus* B (Anderson,[8] Brahdy [9]).

Both these cases were under the care of Prof. L. G. Parsons, who has kindly allowed us to report them, and to him we are very grateful. We would also thank Prof. Lewis and Dr. Ash for their kindness in reporting upon the organisms in both cases.

QUEEN'S HOSPITAL FOR CHILDREN.—At the annual meeting last week the Duke of York, the president, announced that a fund is to be raised for building a new out-patient department to commemorate the generosity of the late Lady Cooper, vice-president, and to be named after her.

CEREBRO-SPINAL FLUID PRESSURES IN SYPHILIS.

BY T. F. HEWER, M.D. BRIST.,
BACTERIOLOGIST IN THE WELLCOME TROPICAL RESEARCH LABORATORIES, KHARTOUM.

It is generally stated in the text-books that one of the commonest and earliest signs of a pathological condition of the cerebro-spinal fluid in syphilis is an increased pressure; indeed, one seldom sees a report on a cerebro-spinal fluid examination in which it is not remarked that the tension was somewhat raised. Very often these observations are based upon a rough estimate of the number of drops which flow from the needle in a minute and, even where a manometer is used, there is such a lack of uniformity of technique that probably very few of the records can be accepted without question. The purpose of this paper is to give an account of the figures reported in the literature, to discuss the technique of manometry, and finally, to publish the results of observations upon the pressures obtaining in a series of some 300 cases of syphilis, in all stages of the disease.

The results of previous investigators may be shown conveniently in tabular form; it should be mentioned that these are the figures obtained by routine examinations of syphilitics in all stages of the disease without clinical signs of neurological abnormality.

Author.	Stage of disease.	Cases.	Percentage with hypertension.	Remarks.
Raynaud et al.[1]	Primary and secondary.	38	36	With Claude's manometer in sitting position.
	Tertiary.	24	37	—
Raynaud et al.[2]	Primary and secondary.	152	38·1	—
	Tertiary.	120	40	
Fleischmann [3]	Primary sero-negative.	27	51·8	Only 37·1 per cent. had pleocytosis.
	Primary sero-positive.	39	48·6	Pleocytosis in 33 per cent.
	Secondary.	135	68·8	Pleocytosis in 50·4 per cent.
	Tertiary.	31	87·5	Pleocytosis in 50 per cent.
Ravaut [3] ..	Secondary.	33	42	Pleocytosis in 88 per cent.
Werther [3] ..	,,	?	82	Pleocytosis in 48 per cent.
Eskuchen [3] ..	,,	?	60–85	—

According to Dujardin,[4] pleocytosis in the primary or secondary stage of the disease is always accompanied, and sometimes preceded, by increase of fluid pressure; and Greenfield and Carmichael [5] state that increase of cells in the fluid in tertiary syphilis is usually associated with an increase of pressure.

It will be seen shortly that the above figures are very greatly at variance from those now reported and I believe that the difference may be explained by a consideration of the many sources of error that present themselves. It will be readily admitted that the favourite bedside method of counting the number of drops that flow from the needle is apt to be grossly inaccurate; one frequently finds, when collecting fluid for examination, that a slight rotation of the needle about its long axis will immediately

Fourteen days later the temperature rose to 102° F., and ain quite suddenly appeared similar swellings in the bcutaneous tissues, one in the region of the left elbow and other in the left submaxillary region. Above the right ee in the line of the great saphenous vein was a hard ep-seated swelling which differed from the other swellings the fact that it was larger, harder, more tender, and only ry slowly resolved. The left elbow- and right knee-joints re swollen, tender, and painful on movement. The elids were swollen and the facial appearance was suggestive nephritis, but there was no albuminuria. There were hæmorrhages into the skin. Another course of hæmostyl jections was given. The joint condition quickly subsided, d the deep swellings, with the exception of the one above e right knee, very soon resolved. The temperature soon l to normal. Forty-eight hours after the last injection hæmostyl the patient developed œdema of both eyelids, t this readily subsided without treatment. This was doubtedly an anaphylactic phenomenon.

During the next four weeks the patient's condition was tisfactory. Then he complained of pain in his right side d his temperature rose to 102·4° F., and pulse-rate 126. pleural rub was audible on auscultation at the right base. small effusion rapidly developed. On the next day rpuric spots appeared on the extremities, and also a w on the face and trunk. A systolic murmur was heard the apex. Hæmostyl was again administered as before d the temperature fell gradually. The effusion quickly solved. A general urticaria appeared after the last jection of hæmostyl. This was an anaphylactic phenomon again. One c.cm. of pituitrin was given and the ticaria disappeared completely in a few hours. A week ter the apical murmur was no longer heard.

Eleven weeks later the patient developed another attack of rexia associated with a deep-seated swelling in the region the left elbow and another near the left knee. Once again ese joints were swollen, stiff, and painful on movement. course of three injections of hæmostyl brought back e temperature to normal five days after onset. and the ep subcutaneous swellings and joint swellings quickly bsided.

Two weeks later the tonsils were removed by dissection. here was no excessive bleeding at operation. The patient ported nine months after tonsillectomy and was found to e in very good health; there had been no further attack f purpura.

During these attacks the blood platelet count was normal. ed cell count showed moderate anæmia, and white cell ount slight leucocytosis which was polymorphonuclear n type. The bleeding time was much lengthened, and he red cell sedimentation was abnormally high. Typical eadings during an attack were: platelets, 210,000 per mm.; red cells, 3,600,000; white cells, 12,800 per c.mm. polymorphs, 87 per cent.). Bleeding time, 4 minutes; red ell sedimentation rate, 66 mm. at the end of one hour. lood culture and urine were sterile during the attacks, and æces contained no abnormal bacteria. During the intervals he bleeding time fell as low as 1 minute and the red cell edimentation rate to 35 mm. per hour.

It is interesting to note that in only two of the ive attacks did cutaneous hæmorrhages appear. This shows that it is by no means invariable for hæmorrhages to occur into the skin; and that it is possible to have damage to the capillary endothelium to a degree sufficient to allow of the passage of plasma only as the sole manifestation of the diathesis. One cannot be dogmatic on the exact nature of all the deep-seated swellings. Many of these, considering their relatively short duration, were most probably caused by exudation of serum alone. Others, and certainly the very hard, tender, and slowly resolving swelling on the right thigh which occurred in the second attack after admission, were most probably due to hæmorrhages.

It is difficult to explain the swinging temperatures accompanying each attack in any other way than by the presence of some infective condition, probably originating in the tonsils. The attack of pleurisy was considered to be an infective condition, and the simultaneous purpuric eruption is significant. The interesting subcutaneous nodules which were observed on admission, and which were found to be due to a low-grade infection of the subcutaneous tissues, tend to confirm the opinion that some infective condition was present, as does the presence of the polymorphonuclear leucocytosis. It is interesting to note the constant improvement resulting from the administration of hæmostyl.

I am indebted to Dr. C. W. Curtis Bain for permission to publish this case, and for his criticisms.

ACUTE OBSTRUCTION OF THE BOWEL PRESENT AT BIRTH.*

By Gavin Dunlop, M.B. Edin.,
HON. PATHOLOGIST TO THE VICTORIA HOSPITAL, WORKSOP.

A PRIMIPARA had a fall when six months pregnant. The fall was followed by an illness lasting about a month, during which there was severe abdominal pain with vomiting. At this time she was not under my care. On recovery she went to term and was delivered. She was attended by a midwife who advised medical assistance to be sought since the child's abdomen was unusually prominent. The midwife declared that she delivered the head and shoulders without any difficulty, but that the perineum tore as the abdomen of the child passed the vulva.

A few hours after birth the child began to vomit meconium, later followed by quantities of bile-stained fluid. Both the breast and fluids by the mouth were refused and there was never any action of the bowels, although on rectal examination some sloughs were brought down on the finger. This made one suspect intussusception, but there was no straining, no passage of mucus, and no palpable tumour. The condition of the child at 2 days' old was so poor as to put operation out of the question, but he lingered on for a week, dying on the seventh day. Post mortem, the abdomen contained gas, but no free fluid. The intestines were everywhere matted together, but the adhesions were not of recent formation and were firm enough to tear the bowel when an attempt was made to separate them. The main obstruction was found in the proximal part of the jejunum, and was caused by kinking of the gut by a band of adhesion. Above the obstruction the bowel was much distended by gas and contained a small amount of bile-stained fluid, but below the stricture it was collapsed and empty. The bowel wall was congested in the upper part, but lower down it presented a normal appearance.

As regards ætiology, my theory is as follows: When the mother sustained her fall during the sixth month of her pregnancy she received a blow on the abdomen, and, as stated above, was confined to bed for a month with abdominal pain and vomiting. It would seem that this illness was an attack of peritonitis whose onset was determined by injury to and lowering of the vitality of her internal organs. If it may be assumed that the placenta either shared in the damage caused by the fall, or was injured by the ensuing infection, then one can believe that its natural protective influence was abolished and that bacteria gained entrance to the fœtal circulation by the blood stream. Unfortunately permission to examine was confined to the abdomen, so it is impossible to say whether there were other lesions to be found in the body of the child besides the signs of peritonitis. The midwife who attended at the birth did not examine the placenta with more than ordinary care, but her statement is that there was nothing unusual except the fact that it was of the battledore type.

* Read before the Royal Medical Society of Edinburgh.

but most are content with remarking that the pressure was raised. Samson Wright[6] gives as normal figures 6 to 12 cm. of water, Purves-Stewart[7] 10 to 15, and Stitt[8] 9·5 to 12 cm. of water. Collier and Adie[9] give no figures but say "normally the fluid escapes drop by drop. If it runs rapidly or spurts out, this is an indication of the increase of cerebro-spinal pressure." Brain and Strauss[10] are the only authorities among those now quoted who draw attention to the influence of a cramped posture upon the pressure reading; they consider the normal limits to be 10 to 20 cm. of fluid.

When there is so little agreement among those who take measurements, and when the rough impression of the rate of flow from the needle is so generally accepted as an adequate record, it is hardly surprising that loose statements are prevalent.

In the above series of 313 cases of syphilis, in which routine examinations of the cerebro-spinal fluid were made, hypertension was the least common abnormality and there was no apparent relation between the degree of pathological change and the pressure of the fluid. In this series there were 20 cases of clinical neurosyphilis and 92 had pathological fluids, but only five showed pressures in excess of 20 cm. of fluid, and one of these was certainly due to congestive heart failure. These figures contrast strikingly with those presented by other authors and are in entire disagreement with the constantly repeated text-book opinion that hypertension is one of the earliest signs of syphilitic involvement of the central nervous system.

It may be objected that for the method I used it is necessary to fix a lower limit for the normal pressure, but if one were to apply a figure of 15 cm. of fluid to the present series, there would still be no agreement whatever between the hypertension and degree of change as estimated by other means.

It should perhaps be mentioned that I have no experience, in this respect, of general paresis or tabes, for those affections appear not to exist among natives of the Sudan; and, further, this paper deals only with syphilis. It is not suggested that increased pressure is not a common or reliable sign in other inflammatory or neoplastic disorders of the central nervous system.

CONCLUSION.

There appears to be little evidence that increased cerebro-spinal fluid pressure is either a common or a reliable indication of syphilis of the nervous system and the constant quotation of this sign in the text-books is the result of inaccurate observation.

I am indebted to the physicians and surgeons of the Sudan Medical Service, more especially to Dr. R. M. Humphreys and Mr. C. Grantham Hill, of Khartoum Civil Hospital, for access to cases under their charge.

Clinical and Laboratory Notes

A CASE OF PURPURA RHEUMATICA.

BY LESLIE E. LUCAS, M.B. EDIN.,
HOUSE PHYSICIAN, HARROGATE GENERAL HOSPITAL.

THE importance of a primary septic focus in cases showing the hæmorrhagic diathesis is still a matter of dispute. Ledingham[1] produced typical purpura hæmorrhagica in animals by injecting anti-platelet serum. Frank[2] and Kaznelson[3] considered the reduction of platelets in purpura to be the immediate cause of the purpuric manifestations. The former regarded the thrombopenia to be due to an aplastic state of the bone-marrow, caused by a toxic body in the spleen. Bedson,[4] however, as the result of work on guinea-pigs, concluded that diminished platelets were not sufficient alone to cause a purpuric eruption, and that some damage to the endothelial lining of the capillaries was necessary in addition. Brill[5] also considered that a simple diminution in the number of platelets was insufficient to cause purpura, and suggested that another factor might be some unknown substance produced by the spleen and acting through the blood. Kidd[6] drew attention to the frequency of a local focus of infection in his series of 24 cases of purpura of the urinary tract and the subsequent improvement on removal of the focus. Subsequent authors have stressed the frequent presence of a septic focus in cases of purpura, while some have associated the disease with a vitamin deficiency of an unknown nature.

The following case of Schönlein's purpura (purpura rheumatica) supports the theory that there is often an infective process acting as a primary cause.

A boy, aged 12 years, was admitted to Harrogate General Hospital on Sept. 22nd, 1930, with a history of a purpuric eruption which had commenced four months previously. At the onset the right knee was reported as being swollen, hot, and tender, but the joint condition subsided entirely in about eight days. For two months his temperature had ranged from 99° to 102° F. Twelve months before admission the patient had an attack of rheumatic fever. There was no relevant family history.

On admission the temperature was 101° F., and pulse-rate 100. The fading purpuric spots were still evident on the forearms and legs. A curious feature was the presence on the upper and lower limbs of numerous hard subcutaneous nodules, each about the size of a hazel-nut. The tonsils were large and not above suspicion as foci of sepsis. A systolic murmur was audible at the mitral area. The spleen was not enlarged. One of the subcutaneous nodules mentioned above was removed, and microscopic examination showed a round-celled infiltration of the subcutaneous tissue, suggesting a low-grade infection. Large doses of salicylates were given and the temperature subsided within 48 hours. The patient made an uninterrupted recovery. The mitral systolic murmur disappeared, and the subcutaneous nodules resolved.

On Dec. 29th the boy had an ingrowing toe-nail removed under a general anæsthetic (ethyl chloride). On the next day his temperature rose to 102·4° F. Quite rapidly large and tender swellings appeared in the subcutaneous tissues in the region of the larger joints of the extremities, most evident at the knee- and elbow-joints. The overlying skin was unaffected. The knee- and elbow-joints were slightly swollen, tender and painful on movement, but there was no redness of the overlying skin. Salicylates were again administered in large doses, and although the temperature persist [illegible] and joint swellings subsided quickly. [illegible] administered. A course of 10 c.cm. [illegible] for three days was given. The temperature quickly fell to normal.

He considered that the duodenal tube might be used more freely by physicians in this country in the treatment of ulcer. The optimum time for operation should be chosen; diabetes and toxic goitre should be controlled before operation was undertaken. Gastric ulcer cases should be prepared for a few days and perhaps given a blood transfusion. Even a peritonitis case should be treated for a few hours to reduce shock and pain. Operation in a hospital or nursing home gave the patient a better chance of recovery than an operation in a private house. Assistants should be available, especially to give the most suitable type of anæsthetic. The mortality in the abdomino-perineal operation for carcinoma of the rectum had been greatly reduced by the use of gas and oxygen and spinal anæsthesia, and he preferred to wait until these were available before undertaking this operation. Every surgeon should consider his own limitations and avoid any operation which he did not feel he was capable of performing. To operate or not to operate was sometimes, for the patient, to be or not to be.

Mr. Sangster Simmond divided the profession into four classes: ultra-medical physicians; excessively surgical surgeons; surgically minded physicians; and medically minded surgeons. So little territory had been left unexplored in the surgical field that young surgeons were reduced to treating medical conditions surgically. The training of surgeons was limited to watertight compartments; few had any experience of general practice, although such experience would be valuable to them. The treatment proposed for gastric ulcer depended on whether the patient happened to be admitted to a medical or to a surgical ward. A borderline ward would be an advantage, under the joint control of physicians and surgeons, in order that they might collaborate on the treatment of the case.

Mr. Neil Sinclair said that when a surgeon opened a patient's abdomen and found, say, gallstones, some calcified glands, a gastric ulcer, and a chronic appendix, it required great restraint to be content with one major operation instead of four. Surgeons should not think of themselves as carpenters; they should keep in touch with medicine.

Dr. Maurice Shaw thought that surgeons were sometimes lured into excessive surgery by the physicians. In a large proportion of cases in which laparotomy was performed for suspected carcinoma of the intestinal tract, nothing abnormal was found. Surgeons were apt to complain that physicians sent them cancer cases too late, but in doubtful cases it was sometimes difficult to persuade the surgeons to operate. They preferred a certainty. He thought there was a place for cholecystostomy in the treatment of an infected gall-bladder. It was often impossible to detect macroscopically whether a gall-bladder was diseased, but quite a large number of normal-looking gall-bladders were not healthy, and simple surgical drainage often relieved the patient. Moreover, if the gall-bladder was left, there was still something more to do if the symptoms did not abate. The duty of the physician included the treatment of the patient with drugs, but few drugs were specific, and he regarded the physician chiefly as a diagnostician. He would like to see the physician confident in the diagnosis of all complaints, and the surgeon proficient in operative technique; it would then be the duty of the physician to tell the surgeon what to do and leave it to his discretion to carry it out.

Dr. O. L. Carden Sibley said that it was the duty of the general practitioner to decide whether the patient required medical or surgical treatment. In the treatment of duodenal ulcer he agreed that the patient should be given prolonged medical treatment, and later, if that failed, be sent to a surgeon for gastro-enterostomy. But after operation he must continue to follow a duodenal diet sheet for months, and possibly years. If sent back to the physician and properly looked after, he would be cured; if not, he would be one of the failures of surgery.

Dr. H. H. Sanguinetti thought that the powers of resistance of the patient should be fully investigated before operation, and in this connexion the opinion of the general practitioner would be valuable.

Mr. F. M. Loughnane said that not enough surgery was being done at the present time. With an enlarged prostate, back pressure might exist without giving rise to symptoms, and that was the stage at which operation was desirable. General practitioners often delayed too long before calling in the surgeon to cases of appendicitis and peritonitis. Hurst admitted that 20 per cent. of chronic gastric ulcer cases died of carcinoma. Among those operated on the proportion was much less. Laparotomy did no harm and made it possible to prevent the onset of carcinoma.

Dr. Howard Stratford considered that there was a good deal of unnecessary surgical interference in the nasopharynx. He had seen few good results from septum operations. It was not merely the turbinals or septum which were at fault in nasal obstruction; the neighbouring sinuses were often chronically infected, and were extremely difficult to treat.

The President said that the development of preventive medicine might ultimately lead to the disappearance of surgery. Children and young adults should have periodic examinations to prevent the development of serious conditions later in life.

Mr. Hamblen Thomas and Dr. Geoffrey Evans replied.—Mr. Zachary Cope said that he thought Mr. Loughnane was unduly severe in saying that the general practitioner called the surgeon in too late to cases of appendicitis. Often in such late cases the general practitioner had only been summoned himself an hour or two before.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

At a meeting held on April 26th, with Dr. Letitia Fairfield, the President, in the chair, Lady Barrett proposed that a group should be formed for the study of anæsthesia in midwifery, the group to be composed of women obstetricians and gynæcologists in London. This proposal was accepted.

Dr. Gladys Dodds then delivered an address on the

Aschheim-Zondek Test.

Tests for pregnancy used in the past, she said, had shown a large percentage of error, but the accuracy of the Aschheim-Zondek test had been confirmed by everyone who had used it. During pregnancy the urine contained œstrin and a hormone secreted by the anterior lobe of the pituitary. It was upon the anterior lobe hormone that the test depended; the hormone stimulated the development of ovarian follicles and ovulation, as a result of which œstrin was secreted. It was non-specific, inducing changes in the ovary of the female and the testis in the male; œstrin, however, was a specifically female hormone. When the urine of a pregnant woman was injected

MEDICAL SOCIETIES

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

AT a meeting of this society on May 4th, with Dr. H. H. MILLS, the President, in the chair, a discussion on

Excessive Surgery

was opened by Mr. HAMBLEN THOMAS, who declared his intention of being provocative. From the early days of history, he said, trephining of the skull had been performed to let out evil spirits; the Assyrians and the Egyptians had practised the operation. In ancient Greece medicine was held in great esteem. Surgery received a fresh stimulus in the sixteenth century from the study of anatomy, and during the seventeenth and eighteenth centuries the study of physiology had advanced. There was a time when the surgeons at some of the large hospitals called on the physicians every morning for orders. When antiseptics and anæsthetics came into use in the nineteenth century a wider range of operations became possible. Some degree of antagonism had existed between physicians and surgeons in the past, but good results were to be hoped from the collaboration of physicians and surgeons in the future, and the coöperation of the family doctor with the surgeon was especially valuable. All operations involved danger, if only from the anæsthetic, and he occasionally wondered whether certain operations were not too extensive. Simple amputation of the breast for carcinoma, to take an example, appeared to give results almost as good as the complete Halstead operation. Mutilated limbs could sometimes be saved from amputation if the vascular supply was good. The phrase "surgical interference" was commonly used, and if interference were carried to extremes every child would have its appendix removed to avoid the chance of appendicitis. Drastic surgery might sometimes be worse than the disease, as in resection of the colon, some cases of gastrectomy, and operations for carcinoma of the thoracic œsophagus. Tonsils were frequently removed from patients in whom nasal trouble had been overlooked. A time might come in the future when all disease would be cured or aborted by medical measures, and only orthopædic and repair work would be left for the surgeons.

A MUTUAL FIELD OF WORK.

Dr. GEOFFREY EVANS said that though there had been antagonism between physicians and surgeons in the past they now worked in collaboration, in London at least. Physicians, although lacking the surgeon's skill with special instruments, such as the cystoscope, were beginning to approach surgeons in their capacity to diagnose surgical conditions, and were supplying patients to the surgeons. Ignoring other aspects of surgery, he wished to consider that field in which physicians and surgeons were watching each other to decide which could do better for the patient. It was excessive surgery to open the thorax or the skull for exploratory purposes, unless the surgeon had some idea where to make the opening. With the abdomen it was less important to know where to make the opening than to have some idea of the nature of the disease. Bleeding from the bowel, for example, might come from an ulcer or a new growth, and operation might cure the patient; on the other hand, if the bleeding came from an arteriosclerotic vessel operation might kill him. Pain was among the causes of excessive surgery and a certain number of operations were performed for functional causes such as spastic colon, because of the pain of the patient and sometimes because of the anxiety of the relatives. Too many operations were performed for adhesions, a diagnosis which was accurate not more than once a year in any considerable practice. Operations were also performed to improve on nature, such as gastropexies and cæcopexies; nephropexy was occasionally advisable and curative, but 'pexy operations as a whole were too often followed by visceral sensations which, if noticed as a sequence to operation, were less amenable to treatment than if noticed before. Peptic ulcers were among conditions for which both medical and surgical treatment were available. A certain number of patients would die of peptic ulcer in any case, whatever treatment was employed. Hurst and Ryle obtained good results with medical treatment, and it was equally certain that the results of surgical treatment were good. If a patient survived two years after operation his expectation of life was probably better than it would have been without operation; but some failed to survive, and 15 to 20 per cent. were not improved by surgical treatment. In his opinion, if death from hæmorrhage or perforation was to be feared, operation should be advised; if not, the patient should be given medical treatment for two or three years, and, if this was not successful, operation could then be performed. In the case of certain organic diseases to which recognised symptoms were attributable, operation sometimes failed to relieve the patient; examples were chronic appendicitis, cholelithiasis, and tonsillitis. Removal of the gall-bladder in cases of cholecystitis might fail to remove the symptoms, and symptoms attributable to chronic tonsillitis were not necessarily due to infected tonsils. In an appreciable number of cases symptoms usually attributed to the respiratory tract were due to hyperchlorhydria. Faulty posture, atmosphere, and diet might all play a part in producing symptoms. Surgery, in his opinion, was not excessive at the present time, but he feared lest it should be in the future. The patient should be examined thoroughly by his doctor before being recommended for surgical treatment.

THE CHOICE OF THE PATIENT.

Mr. ZACHARY COPE said that physicians were of two kinds: those who were conservative and looked upon surgeons as their natural enemies, and those who inclined towards excessive surgery, and expected the surgeon to achieve the impossible. The patient could always refuse to have an operation, and it was no part of the surgeon's business to tell him he would die unless he submitted to it. The surgeon might be mistaken in his opinion; patients with symptoms of obstruction of the small intestine having refused operation and taken castor oil had recovered. Surgery should not be recommended merely because something abnormal was discovered, such as a lipoma which was occasioning the patient no discomfort. Every man over 50 or 60 had an enlarged prostate, but this did not require to be removed unless it was affecting the condition of the kidneys or interrupting his life in any way. Operation should not be performed for any condition amenable to medical treatment until medical treatment had been thoroughly tried. But in some cases operation might be hastened for economic reasons, for example, where a patient with gastric ulcer was likely to lose his job as a result of needing recurrent periods of medical treatment.

REVIEWS AND NOTICES OF BOOKS

Manipulative Surgery.

By A. S. BLUNDELL BANKART, F.R.C.S., Orthopædic Surgeon, Middlesex Hospital, Royal National Orthopædic Hospital, and Hospital for Epilepsy and Paralysis, Maida Vale. London: Constable and Co. 1932. Pp. 150. *7s. 6d.*

Mr. Blundell Bankart's aim has been to give a brief and intelligible account of some of the uses and abuses of manipulation in surgery. To this end he has included an account of those pathological conditions—excluding fractures and dislocations, and deformities such as club-foot—which most often call for manipulation in the course of their treatment. The general practitioner, for whom the book is primarily intended, is thus provided not merely with a narrow description of a particular method of therapeutics, but with guidance in the diagnosis and treatment of some common surgical affections. The author deals in general terms with sprains and adhesions, the postural activity of muscles, postural deficiency, torsion injuries, subluxation of joints, various forms of arthritis, and the general principles of manipulation with a note on its dangers and failures. Separate sections are then devoted to the foot, with special emphasis on foot strain; the knee; the hip; sprain of individual muscles and tendons in the lower extremity; the spine and pelvis; the fingers, hand, and wrist; the elbow and the shoulder. The last two sections of the book are devoted to a discussion of bone-setting and osteopathy, and to a concluding chapter which summarises arguments previously set out.

Of especial interest is the pronouncement that uterine displacements and intrapelvic diseases do not give rise to localised pain and tenderness over the back of the sacro-iliac joint, but that gynæcological operations often do put a very great and unnatural strain on the joints of the pelvis and lumbar spine. Mr. Bankart states categorically that uncomplicated sacro-iliac strain does not cause pain along the course of the sciatic nerve, and that "sciatica" is nearly always associated with spinal arthritis. Sacro-iliac strain can generally be cured by manipulation or if this is not successful by arthrodesis of the joint. He condemns the common practice of treating these cases with rest, local applications, massage, and exercises (without preliminary manipulation) and "sacro-iliac supports." Lumbar back-strain, which is the next common cause of low back pain, also responds to manipulation, but lumbo-sacral pain does not. Manipulation combined with efficient physiotherapy may be expected to benefit appreciably about half the cases of spinal arthritis with or without secondary sciatica.

For Mr. Bankart's views on the indications for manipulative surgery in various lesions of the joints of the limbs reference must be made to his book, where the appropriate technique is fully explained and illustrated. Here we need only note that he writes with lucidity and force, and that his book will be invaluable in helping to dissipate the atmosphere of mystery which bone-setters have allowed, and indeed encouraged, to become associated with their names. Though he has some hard things to say, the author does not say them in any spirit of vindictiveness. There is no reason why he or any orthopædic surgeon should be vindictive, but he shows that the interpretation which bone-setters themselves place on their clinical findings cannot be upheld on any anatomical or physiological grounds.

In the introduction of the book the physiological considerations underlying some of the general principles of orthopædic surgery are discussed in a highly illuminating manner and the same standard is maintained throughout.

This is indeed an admirable little book.

Genetic Principles in Medicine and Social Science.

By L. HOGBEN, M.A., D.Sc., Professor of Social Biology in the University of London. London: Williams and Norgate, Ltd. 1931. Pp. 230. 15*s.*

Prof. Hogben is always readable and usually interesting, and he has now written a book which should be important if some of those concerned will take what he says to heart. Briefly, his argument is that we now know enough about human inheritance to be sure that in some instances the genetical principles worked out on animals apply also to man, quantitatively as well as qualitatively, that the fanciful antithesis between nature and nurture must be given up, and that scientific inquiry has now advanced to the stage where research is justified and propaganda is not. He desires in short that the study of human genetics should be removed from the atmosphere of the drawing room to that of the laboratory, and that sincere scientific investigation should replace amateur political speculation. He believes, for example, that most of what has been said and written in recent years about the incidence and possible control of feeble-mindedness is superficial and misleading, that a single-gene hypothesis will not explain the whole of its genetic origin, and that there is clear evidence that Mongolian idiocy is largely due to environmental factors. We are not surprised therefore to find that he objects to what he frankly calls the aristocratic bias in which eugenists have so freely indulged and begs them to be a little more sure of the facts before they clamour for practical action. In particular he points out in several places how the medical profession can help in accumulating the data which are so much needed, and his book certainly ought to stimulate a number of people to take a hand in so good a cause.

Artériographie des membres et de l'aorte abdominale.

By REYNALDO DOS SANTOS, Professor of the Faculty of Medicine of Lisbon, Surgeon to the Hospitals; and A. C. LAMAS and J. P. CALDAS, both Surgeons to the Hospitals, Lisbon. Paris: Masson et Cie. 1932. Pp. 192. Fr.45.

THE pioneer work of certain Lisbon surgeons on the injection of arteries in the living subject has excited widespread interest. It has been developed so far afield as Japan where an oily medium for the opaque substance has, it is claimed, obviated certain dangers and made anæsthesia unnecessary. In an interesting little book Prof. dos Santos and two surgical colleagues admit the drawbacks which attend the use of lipiodol. Their own early work was carried out with uroselectan and abrodil, but they now extol the virtues of a new thorium compound of which the injection is said to be painless. By puncturing the vessels, mostly under anæsthesia, which is unnecessary with the thorium compound, the authors have examined 300 cases, ranging from gangrene of the limbs to aneurysm of the aorta, and they describe into immature mice, it produced ovarian changes which could be used for the diagnosis of pregnancy. The exact day on which the anterior lobe hormone first appeared in the urine of a pregnant woman had not been ascertained, but it was present by the third day after the first missed menstrual period, and it was thought to appear after embedding of the ovum. The amount of hormone secreted in the urine increased rapidly, and reached a maximum during the first two months of pregnancy; it disappeared on about the eighth day of the puerperium. The œstrin in the urine increased more slowly, and reached a maximum between the third and seventh months; it also disappeared on about the eighth day of the puerperium. Five immature female mice, each weighing 6 to 8 g. were used in making the diagnosis, and received injections of 5 c.cm. of urine over a period of three days; they were killed 100 hours later, and the ovaries examined. If the result was positive, certain typical changes would be found which were diagnostic of pregnancy in the patient. The test was valuable in distinguishing the amenorrhœa of pregnancy from amenorrhœa due to other causes. Fibroids complicating pregnancy sometimes led to difficulties of diagnosis. In pulmonary tuberculosis, heart disease, or chronic nephritis the test was particularly useful in establishing the diagnosis of pregnancy early; it could also be used in making the differential diagnosis between ectopic gestation and acute salpingitis or adnexal tumour. A positive result was not proof of a living pregnancy, but only of living placental tissue. In the presence of hydatidiform mole and chorion epithelioma the test was often positive with unusually high dilutions of urine. The greater the dilution the greater was the suspicion of some abnormality of the placental tissue. If the test had become negative following delivery, and subsequently became positive again, there was a strong suspicion that chorion epithelioma was present. She described a case of this kind in which pan-hysterectomy had been performed; the Aschheim-Zondek test had again become negative following the operation, and had remained negative ever since. There had been no sign of recurrence.

Dr. DULCIE STAVELEY then spoke on the

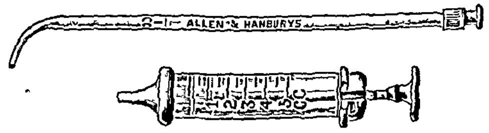
Diagnosis of Pregnancy by X Rays.

The fact of pregnancy, she said, was usually established before X rays were used. For diagnostic purposes radiography had little value before about the sixteenth week, though in the United States it was claimed that a diagnosis could be made at the fourteenth week. Usually X ray examination was used to confirm the diagnosis. A method of injecting lipiodol into the uterus in order to make an earlier diagnosis was said not to cause abortion, but it only showed a rounded swelling in the wall of the uterus, which was not in itself diagnostic of pregnancy. Adiposity of the patient might help to obscure the picture, and a lively baby sometimes spoiled the film by moving. The spine was the first part of the fœtus to become visible upon X ray examination and showed first as a row of stippled dots; patches of calcification in a fibroid might be confused with the early appearance of the spine. The maturity of the fœtus could be estimated by the size of the spine and skull, and by the appearance of the various bones in the skiagram. The os calcis appeared between the twenty-first and the twenty-ninth week, the astragalus between the twenty-fourth and the thirty-second week, and the epiphysis of the femur at about the thirty-sixth week. In a post-mature fœtus the epiphysis of the upper end of the tibia might be seen. Estimation of maturity, however, could not be made more accurately than within a fortnight. X rays were valuable in clearing up the diagnosis in cases of suspected multiple pregnancy. A dead fœtus could often be recognised by a sagging attitude, overlapping of the cranial bones and by the fact that no growth was seen to have taken place when a second examination was made after an interval; often, too, the fœtus would be found to be in exactly the same position at the second examination as at the first. Malpresentations such as breech with extended legs, face, and transverse presentations could be demonstrated by radiography. The placenta was not normally visible, but it might show calcified patches, and these might be useful in the diagnosis of placenta prævia. Abnormalities in the mother, such as lordosis, scoliosis, spondylitis, osteomalacia, or deformities of the pelvis or hip-joint could be demonstrated. Disproportion between the head and the pelvis could not be demonstrated well by a lateral view, but recently it had been made possible to take a vertical radiogram, showing the fit of the head in the pelvis, and measurements could be made against a calibrated scale. Abnormalities of the fœtus such as anencephaly, hydrocephaly, and even spina bifida might be demonstrated radiographically before birth. Dr. Staveley showed lantern slides of radiograms of the conditions described.

NEW INVENTIONS

A NEW URINOMETER PIPETTE.

THE urinometer pipette here illustrated has been found very convenient for use with the urinomete of Doremus. Instead of a teat there is a butt a the end which will fit on to an all-glass or Record syringe. It is graduated as usual to deliver 1 c.cm In use, the syringe and pipette are assembled and the urine is drawn up into the pipette, any exces being expelled. The urine can then be slowly delivered into the urinometer in the usual manner The advantages gained by the use of this combination over the ordinary pipette and teat are as follows (1) As the urine can be expelled slowly there is no reflux of the nitrogen into the short limb of the urinometer and thence its escape through the bulb into the air. This is a common experience when the teat is used and must vitiate the result of the estimation which may be important when the percentage of urea is small. (2) If the urinometer has not been recently used and reliance is placed on the teat it may be found that it has perished and spare teats may have likewise perished or be too small. (3) Time is saved as the teat has not to be manipulated down the pipette until the 1 c.cm. mark is reached if there is any excess urine drawn up. The illustration depicts a 5 c.cm. syringe, but for use with the urinometer of Doremus only a 1 c.cm. syringe is required. The combination as illustrated might be made use of when any small quantity of fluid is required; for instance, in measuring the urine when Gerrard's urinometer is used; but in that case a longer pipette would be required.



Messrs. Allen and Hanburys, Ltd., Wigmore-street, London, W., are the makers.

Digitalin Granules "A. & H.," a British preparation, consist of the *Digitaline cristallisée* of the French Pharmacopœia. This substance is the most active principle of digitalis leaves, and, because of its reputation for uniform activity, it has long been popular, particularly on the Continent. Its use is recommended by high authority in cases where galenical preparations of digitalis have failed.

For Prescribing:
In tubes, containing 40 granules, 2/6 each
For Dispensing:
In bottles, containing 250 granules, 12/6 each
Subject to the usual professional discount.

Descriptive literature and clinical trial sample will be sent post free on application.

[See also pp. 13, 28, & 29.]

also a great deal of work done in abdominal investigation. Some of the most striking results are to be seen in the diagnoses of kidney conditions. The illustrations are clear and documented; radiograms taken at the time of injection are accompanied by a description of symptoms, and a note of the method of injection and of the results obtained from the reading of the radiogram. Throughout the book it is emphasised that the method is safe, at least in experienced hands, and whilst the authors regard it as of great value, they point out modestly that they are only building up their experience and are not dogmatic as to the results.

It is obvious, we think, to anyone who reads the book carefully, that new horizons of investigation and diagnosis have been opened by this work. It is difficult to convey the curious results of the opaque injection of arteries to anyone who has not been fortunate enough to see the radiograms. For diagnostic purposes such conditions as the displacement of an artery by a tumour can be shown, and occasionally the abnormal formation and distribution of vessels in sarcomata can be observed. The book is written in French and has a short preface by Prof. Leriche. The illustrations are mostly well reproduced.

Schizophrenia (Dementia Præcox).

An Investigation of the Most Recent Advances. By Various Contributors. London: Baillière, Tindall, and Cox. 1931. Pp. 246. 21*s.*

THE earlier volume on schizophrenia in this series is now supplemented by the collection of papers, read in 1929 at the tenth annual meeting of the Association for Research in Nervous and Mental Disease. The clinical section opens with a paper by Malamud and Rothschild on the permeability of the barrier between blood and cerebro-spinal fluid, examined according to Walter's method; the distribution-ratio of the bromide was found to be high in a majority of the 210 cases examined, and the general findings of the German workers were corroborated. The deficiency of catalytic iron in the ganglion cells of the cerebral cortex in schizophrenia is confirmed by W. Freeman, who refers to the earlier investigations of Koch and Mann. P. J. Trentzsch writes briefly on the results of testing the circulatory system in the usual way; his conclusions are too far-reaching. A somewhat banal essay by Macfie Campbell pleads that the benefit of the doubt be given to environmental factors in the ætiology of psychosis. An unfinished statistical study of prepsychotic personality by Bowman and Raymond yields a number of interesting findings, some of them running counter to current teaching. Jelliffe's article on Vigilance, Motor Pattern and Inner Meaning is rather a hotch-potch, being an unsuccessful attempt at synthesis; the careless style makes it difficult to read.

A sober sketch of the position with regard to anatomical findings in schizophrenia, by the Munich pathologist, W. Spielmeyer, is followed by H. S. Sullivan's brief reassertion of the familiar rule that a stormy onset in schizophrenia suggests a favourable outcome. A more serious study of prognosis is that of E. A. Strecker, amplifying his earlier report; the cases of 25 schizophrenic patients who recovered are examined in detail. G. Zilboorg presents a paper on treatment, viewed as a matter of affective reintegration; it covers more than its subject, and is ill-grounded in its assertions about the nature of schizophrenic thought-disorder; it is a psychoanalytical study, argument being based on the single instance. A summary of the results obtained by different methods of treatment, by L. E. Hinsie, and a report on the effect of sodium amytal as a narcotising agent in 15 cases of catatonia, by W. J. Bleckwenn, conclude the volume. After nearly all the papers a verbatim account is given of the discussion which followed.

The book is uneven in quality, but it bespeaks the wide range and activity of research into this problem that is going on in the United States.

Views and Reviews.

First Series 1884–1919. By HAVELOCK ELLIS. London: Desmond Harmsworth. 1932. Pp. 322. 10*s.* 6*d.*

THIS volume contains thirty-two hitherto uncollected essays arranged in chronological order and covering a period of 35 years—1884 to 1919—in the life of the distinguished humanist. A chronological series of essays by a man of numerous interests and wide culture must make disorderly reading, inasmuch as at an average of every ten pages the subject changes entirely. Mr. Ellis in a prefatory note acknowledges that the essays are so various in character that they cannot be classified, the one thing that they have in common being "that it has never proved possible to fit any of them into my books." Some of them seem hardly to be worth resuscitating, but others make enjoyable reading, and often the date is of significance, inasmuch as the period in which an article was written may supply interesting sidelights on the matter discussed. A second series will follow including essays which appeared between the years 1919–1932.

The Philosophy of Sport.

By P. MCBRIDE, M.D., F.R.C.P.E., F.R.S.E. London: Heath Cranton, Ltd. 1932. Pp. 190. 7*s.* 6*d.*

THESE chapters on sport in its various aspects make interesting reading; the reflections are based on personal experience and cover a wide range, inasmuch as the author enjoyed unusual opportunities for the exercise of many diversions. In a summary of the developments of sport during the past 50 years, contributed recently by Lord Desborough to a series of articles in the *Times*, the question was raised whether the word "sport" should include games, or should be confined to such varieties as implied the pursuit of a quarry. In the greater part of Dr. McBride's book he follows the latter definition, being very interesting in regard to fishing, shooting, and hunting, but nearly silent in respect of the playing of ball games. He recognises, however, that for reasons of economy the number of those who can engage in the sport that demands a quarry must be small compared to the number of those who can take their exercise and gain their amusement at football, cricket, or golf, and in discussing the growth and decline of sporting tastes and the British attitude towards sport he is informing. In one chapter he gives a scheme of physical culture, derived from Mr. Bruce Sutherland, into which he has introduced certain modifications, which is certainly rather an excrescence on the scheme of the book, but is justified by the medical authorship. Most of the exercises laid down are familiar, but they are set out very clearly, and there is no doubt that regular practice in them would often conduce to improvement in health.

THE POWERS OF MINISTERS.

PUBLIC opinion has long been uneasy about bureaucracy and the undying rule of D.O.R.A. To various citizens bureaucracy variously means the arbitrary usurpation of legislative or judicial functions, the too paternal limitation of our liberties and simple pleasures, the intolerable infallibility of all jacks-in-office (whether the office is central or local), and the intrusive importunities of the tax collector. As to the survival of D.O.R.A., we vaguely understand that the Defence of the Realm Acts and Regulations, operating only for the duration of the war, have expired, though several elements of permanent value have been incorporated in the statute-book as post-war Acts of Parliament, the Dangerous Drugs Act of 1920 being an obvious example. It is unfair to scold the Civil Service for matters of policy. The irritating restriction on the sale of chocolates in theatres was the direct and deliberate decision of a post-war Parliament: the same is true of the "permitted hours" for the sale of alcohol. But, if some of our complaints against bureaucracy must be laid at the door of Parliament, there is nevertheless a popular impression that Whitehall takes too much upon itself. When our Civil Servants were solemnly indicted by so brilliant an advocate as the Lord Chief Justice, some notice had to be taken. In the Donoughmore Committee on Ministers' Powers the Lord Chancellor assembled a strong tribunal of investigation. Its report (Cmd. 4060. 2*s*. 6*d*.), if in places discursive and didactic, is almost the first effort to face the problem: it tells us how far our complaints are justified.

The first half of the inquiry concerned delegated legislation. Is the system of departmental rules and orders improper? Has it been abused? The report declares it to be inevitable; the senior Parliamentary Counsel testified that, if we must have all the new legislation which the country is supposed to want, Parliament itself cannot cope with the task unaided. The Committee assures us that the practice is not unconstitutional. How could it be? Parliament cannot simultaneously surrender its functions to a Minister and complain that he usurps them. Nor is the system new: official statistics surprisingly showed that fewer Statutory Rules and Orders have been registered annually in the past few years than in many years before the war. But, if the quantity is not increasing, the scope is changing. The advantage of flexibility and experiment, the technicality of the subject matter and the impossibility of foreseeing all contingencies and local conditions—these explain the convenience of delegated legislation. The pressure on Parliamentary time, it is admitted, means the progressive incapacity of Parliament as a legislative machine. If Bills are to pass, short cuts are necessary. When, for instance, the Mental Treatment Act instituted temporary treatment for mental patients, it left the Board of Control to make a code for the conditions of their detention. Finally, in face of genuine emergencies—a great war, a general strike, or a financial crisis—the common sense of Englishmen will tolerate exceptional methods. Plague in the Baltic in 1710, cattle distemper in 1746, and cholera in 1832 provided precedents for delegation. Remarkable recent examples, for imposing salary cuts or for taxing imports, are justified, if at all, by the emergency. Yet even here Parliament advertises its legislative failure. The bundle of Orders in Council under the National Economy Act, which played havoc with the statute-book last October, might just as well have been enacted by Parliament itself if the machine could work as swiftly as when it lately passed the Act to indemnify Presidents of the Board of Trade. In pronouncing delegated legislation to be not only convenient but also necessary, the Committee rightly insists upon safeguards. The greatest of these are the power to fix responsibility upon the Minister and the power of the law courts to quash a regulation as ultra vires. Proper publicity and prior consultation with interests concerned are other sensible precautions. The Committee recommends, too, a new and special Parliamentary scrutiny both of Bills which propose delegation and of the departmental rules and orders which flow therefrom. The work of scrutiny will probably fall mainly on the officials of the two Houses, but the principle will serve to remind the members themselves of the duty of vigilance.

The second half of the inquiry concerned the quasi-judicial functions entrusted to Ministers and departmental tribunals, often to the exclusion of the judges' jurisdiction. The medical profession is well aware of this process in the operation of the National Health Insurance Act. Naturally the central and local administration of matters like housing and public health requires the enforcement of standards which are more a matter of social policy than of judicial interpretation. In appeals on questions of reasonable fitness for human habitation, house drainage, or sanitary accommodation, the Minister has the last word. His punitive power over panel practitioners is great. It has been complained too that his procedure is peculiar, for instance, in deciding upon boundary extensions or slum clearance orders. A visible inspector may hold a local inquiry. After hearing evidence which is often irrelevant, he reports in secret to an invisible and anonymous body which reaches conclusions partly judicial, partly administrative; finally the department announces its decision without necessarily giving reasons or following precedents. Notwithstanding certain judicial dicta in the Arlidge case, the Donoughmore Committee advises the publication of inspectors' reports. It lays down valuable principles as to the elements of natural justice which departments must respect. A Minister ought not to be a judge in his own

The debilitated patient & the athlete

are alike in one respect—they both need:

(a) immediately accessible energy: i.e., glucose

(b) elements to nourish and control their nerve cells and reflexes: i.e., calcium & phosphorus

(c) vitamin D to ensure the assimilation of these elements

Glucose-D contains all these components

Whenever glucose is prescribed, whether for the treatment of acidosis or febrile illnesses or as a "nutrient tonic" for debilitated or overstrained adults and children, Glucose-D, the *re-inforced* glucose, is the preparation of choice.

ANTIVIRUS THERAPY

LABORATORY INVESTIGATIONS have shown that bacteria cannot grow in filtrates of their own broth cultures. The "inhibitory" substance is called Antivirus.

CLINICAL EXPERIENCE has shown that local infections heal rapidly when antivirus, made from the responsible or associated organisms, is applied to them. In practice antivirus acts, not only as a specific antiseptic, but as a means of increasing the resistance of the body cells at the site of infection.

THE APPROPRIATE ANTIVIRUS brings about the rapid healing of boils, carbuncles, abscesses, sinuses, infected wounds, and septic cavities. It can be applied by means of a spray, or on lint, to any accessible local infection.

ANTIVIRUS THERAPY is *easy and effective.*

Naturally the central and local administration of matters like housing and public health requires the enforcement of standards which are more a matter of social policy than of judicial interpretation. In appeals on questions of reasonable fitness for human habitation, house drainage, or sanitary accommodation, the Minister has the last word. His punitive power over panel practitioners is great. It has been complained too that his procedure is peculiar, for instance, in deciding upon boundary extensions or slum clearance orders. A visible inspector may hold a local inquiry. After hearing evidence which is often irrelevant, he reports in secret to an invisible and anonymous body which reaches conclusions partly judicial, partly administrative; finally the department announces its decision without necessarily giving reasons or following precedents. Notwithstanding certain judicial dicta in the Arlidge case, the Donoughmore Committee advises the publication of inspectors' reports. It lays down valuable principles as to the elements of natural justice which departments must respect. A Minister ought not to be a judge in his own

The debilitated patient & the athlete

are alike in one respect—they both need:

(a) immediately accessible energy: i.e., glucose

(b) elements to nourish and control their nerve cells and reflexes: i.e., calcium & phosphorus

(c) vitamin D to ensure the assimilation of these elements

Glucose-D contains all these components

Whenever glucose is prescribed, whether for the treatment of acidosis or febrile illnesses or as a "nutrient tonic" for debilitated or overstrained adults and children, Glucose-D, the *re-inforced* glucose, is the preparation of choice.

ANTIVIRUS THERAPY

LABORATORY INVESTIGATIONS have shown that bacteria cannot grow in filtrates of their own broth cultures. The "inhibitory" substance is called Antivirus.

CLINICAL EXPERIENCE has shown that local infections heal rapidly when antivirus, made from the responsible or associated organisms, is applied to them. In practice antivirus acts, not only as a specific antiseptic, but as a means of increasing the resistance of the body cells at the site of infection.

THE APPROPRIATE ANTIVIRUS brings about the rapid healing of boils, carbuncles, abscesses, sinuses, infected wounds, and septic cavities. It can be applied by means of a spray, or on lint, to any accessible local infection.

ANTIVIRUS THERAPY is *easy and effective.*

The TASTELESS & INODOROUS high concentrate of vitamins A & D

The application of vitamins A and D prophylaxis and therapy has been hindered by the technical difficulty of preparing a sufficiently high concentrate of both vitamins together in a tasteless and inodorous form. In Adexolin Liquid, which has been standardised to have twenty times the vitamin A and D concentration of high grade cod-liver oil, this difficulty is now overcome. Adexolin Liquid has no taste or smell.

In Phials (approx. 8cc.) with dropper, 2/6
2 oz. bottles, 12/6.
Usual professional discount.
Dispensing sizes also available.

ADEXOLIN
LIQUID

Also Adexolin Capsules—a still higher concentration of vitamins A and D presented, for convenience of administration, in 3-minim capsules.
Boxes of 25 - 3/9. Boxes of 100 - 12/6

the under 5 group would include more positive actors than any group of the same size composed older children. Whereas the immunisation of 00 children below 5 might create as many as 0 or 600 fresh immunes, in the older age-groups e fresh immunes produced might not exceed 300 400 per 1000 "immunised," depending in each se upon the environment and social status of e children treated. It is clear that a smaller rcentage of mass immunisations of young children ust be more valuable as a preventive measure han a larger percentage carried out upon older ubjects. Godfrey remarks that the evidence hether active immunisation does or does not revent the individual from becoming a carrier equivocal. In any case, he thinks, the reduction f the carrier-rate is probably a relatively nimportant factor, and indeed—since carriers "tend to develop carriers and presumably mmunity, whilst cases have a much greater endency to develop new cases"—the carrier, lthough a chief source of infection, may be egarded "as the cheapest source of naturally cquired immunity." In another paper Dudley[4] lescribes some interesting observations at reenwich Hospital School, the source of many aluable contributions to the epidemiology of liphtheria, upon latent infection with *C. diphtheriæ*. Although there is as yet no satisfactory evidence than an avirulent strain of diphtheria bacilli may acquire virulence, it is generally accepted that the reverse may happen. Dudley thinks that the anomalies which he found in the distribution of latent infections and Schick immunity in this semi-isolated community may be satisfactorily explained upon the hypothesis that when a Schick susceptible is infected with virulent diphtheria bacilli the latter often acquire avirulence. It is to be hoped that further observations may be carried out in order to show with what frequency this loss of virulence occurs amongst infected Schick positives in the general community.

Discussing the relative value of some diphtheria prophylactics, Dudley[1] insists that comparative tests should be made upon groups which not only have the same original Schick reaction frequencies but which, during the time of their immunisation, live under identical conditions, especially as regards risk of infection with virulent diphtheria bacilli. In the earlier days of immunisation the prophylactic used was toxin mixed with antitoxin (T.A.T.) in such a way that toxin was slightly in excess. T.A.T. is still used in America, but there, as in other countries, it is being or has been replaced by some preparation of toxoid (Glenny), the anatoxin of Ramon. Not only is toxoid free from the objections which have been urged against T.A.T.—its liability to dissociation of toxin under unsuitable conditions of storage, and the possibility, largely theoretical, of producing sensitisation to horse serum—but, as Dudley points out, it is a much more powerful antigen. He quotes the results of W. T. Harrison, G. F. and G. H. Dick, G. Ramon, and himself, which go to show that 94 to 97 per cent. of susceptibles, whether adults or children, who received toxoid became negative Schick reactors within a few months. In Harrison's experience any batch of toxoid immunised about 30 per cent. more children than any batch of T.A.T. It has been objected, however, that toxoid at full strength, especially in adults, gives rise to troublesome reactions. In this country, in order not to diminish or even extinguish totally the very feeble flame of enthusiasm for active immunisation, it has been considered important to use prophylactics which caused an absolute minimum of reactions. Ramon and Debré[2] hold that this objection to toxoid (anatoxin) has been greatly exaggerated. They claim that millions of injections have been followed by a very small percentage of slight reactions and by a trifling number of somewhat more severe happenings, and are satisfied that in France such reactions as occur cause no concern either to the doctors or the public. Ramon and Debré deprecate this fear of reactions, and think that the modified prophylactics such as toxoid-antitoxin (T.A.M.) and toxoid-antitoxin floccules (T.A.F.), both of which are widely used in this country, possess no advantages over anatoxin. Dudley finds not only that the reactions following toxoid are more frequent age for age than after floccules, but that the reactions following Ramon's toxoid were more intense than those caused by English toxoid, whereas the immunising powers of the French and English preparations were equal. He considers that in the case of adults and protein-sensitive reactors, in whom toxoid may produce very unpleasant symptoms, floccules should always be used when available. The ideal prophylactic would, of course, be one which as the result of a single symptomless injection produced solid immunity in a short time. Ramon and Debré refer to the work of Claus Jensen, who succeeded in preparing a concentrated toxoid of such high antigenic value that the injection of 1 c.cm. into 100 Schick-positive children rendered 91 per cent. immune in a month. Whilst applauding this success they point out that it would be necessary to prepare about 60,000 litres of ordinary toxoid (anatoxin) in order to furnish sufficient of the concentrated product to immunise 1,000,000 children. If three injections of Ramon's standard preparation were used, only 3000 litres would be required.

In order to simplify and popularise immunisation the introduction of the antigen by routes other than subcutaneous or intramuscular has been tried. Oral administration of anatoxin was shown by Ramon and C. Zoeller (1926) to be valueless. The inferiority of the oral route in the case of scarlet fever toxin has recently been demonstrated by the Dicks.[5] These observers found that the ingestion of an average total exceeding 8,000,000 skin test doses per person only immunised 73·1 per cent. of a series of Dick-positive reactors, whereas when the same toxin was injected subcutaneously into another series of susceptibles a total of 135,500 skin test doses per person converted 93 per cent.

[5] Jour. Amer. Med. Assoc., April 23rd, 1932.

cause. It advocates supervision by the High Court wherever it can be alleged that the Minister or departmental tribunal has exceeded statutory powers. It recommends a right of appeal on points of law; but not on points of fact. And, to simplify recourse to the law courts, the Committee advises that the Crown Proceedings Bill be passed into law and that the archaic procedure of certiorari, mandamus, and the like be replaced by something more modern and less cumbrous.

In both parts of its inquiry the Committee's report, after opening our eyes to the gravity of the problem, is reasonably reassuring. The situation contains elements of danger; safeguards are necessary; but as yet there has been no serious abuse. Part of the trouble, we are told, comes from the obscurity of the language of statutes. Some of the departmental rules and regulations, it is added, are framed by departmental legal advisers who are not as careful as the Parliamentary Counsel to avoid exceeding statutory powers. This is strange. The now much enlarged office of the Parliamentary Counsel is largely recruited from the departmental legal advisers; the latter must always be in constant touch with the former; why cannot the departmental advisers be brought up to a uniform high standard? On the whole the Donoughmore Committee makes us feel that we know the worst. Parliament, says the report, has not realised the extent of its surrender. The warning is useful. Lord HEWART is thanked for sounding the alarm, but the conspiracy theory, set forth in the "New Despotism," is definitely found to be without a shred of evidence. The departments are discharged without a stain upon their character but are told to be more careful in future.

◆

THE PREVENTION OF DIPHTHERIA.

IN this country active immunisation as a communal measure of protection against diphtheria makes but slow progress. Yet Surgeon-Captain S. F. DUDLEY[1] believes that if as many as 80 or 90 per cent. of children under 10 years of age could be maintained Schick-immune, diphtheria would for practical purposes vanish within five years. This view is founded on results already obtained elsewhere. Ample evidence is now available that the incidence of diphtheria can be reduced to negligible proportions by immunisation on a sufficiently large scale. In Canada, for example, according to M. M. G. RAMON and R. DEBRÉ,[2] nearly 1,000,000 people out of a population of 10,000,000 have been immunised, with the result that diphtheria morbidity has been reduced by nine-tenths. But when individual cities are compared it appears that the production of a high aggregate of immunes of all ages is not nearly so effective in reducing the incidence of diphtheria as is concentration of effort—though not to the exclusion of other age-groups—upon children of pre-school age. DUDLEY compares the results of intensive anti-diphtheria campaigns recorded by J. G. FITZGERALD, of Toronto, and by M. A. ROSS and N. E. MCKINNON, of Hamilton, Ontario. In Toronto, although a full immunisation course was followed by the practical eradication of diphtheria from the group protected, there was no evidence that the total diphtheria morbidity had fallen. This, DUDLEY suggests, is because only a third of the school-children and apparently no pre-school-children were protected. He concludes that the proportion of the school population immunised was too small to afford any indirect protection to the uninoculated. In Hamilton, a city of 129,000, the average annual incidence of diphtheria between 1905 and 1924 was 284 per 100,000. In 1925 an intensive campaign resulted in the immunisation of some 26,000 children in the school and pre-school groups and a drop in the morbidity-rate to nine per 100,000 during each of the years 1927 to 1930. In Hamilton, not only was a greater proportion of school-children immunised than in Toronto, but relatively as many of the pre-school-children were also protected. From these data DUDLEY deduces that immunisation of the pre-school group is of supreme importance. His deduction is borne out by the observations of E. S. GODFREY[3] who from a study of the experiences of cities in New York State during the past nine years concludes that to produce a definite effect upon the incidence of diphtheria it is not enough that children between 5 and 14 should attain a high degree of herd immunity. GODFREY cites examples to show that when the immunisation of 30 per cent. or more of children under 5 is superimposed "there is an immediate and definite decline in the current prevalence of diphtheria." He finds that in order to affect the diphtheria-rate favourably this critical proportion must be attained and sustained. In only two instances known to him has a community that had attained the 30 per cent. immunisation-rate of its under 5 age-group suffered even a moderate epidemic. He sees no reason to believe that immunisation *confined* to this group would be equally effective, and he also thinks it possible that immunisation of this group should be largely concentrated in sections of highest prevalence or—when it is not prevalent—in congested areas.

GODFREY suggests that the reason why immunisation of a small fraction of the under 5 group has a greater effect than immunisation of a large fraction of older children may be that atypical, larval cases, which are never diagnosed, exist in greatest numbers in this youngest group, and in this connexion he calls especial attention to the danger of an unrecognised case of nasal diphtheria. Although it is not definitely stated in his paper it seems from internal evidence that Schick tests were not, as a rule, carried out. Thus, in both the age-groups in question a number of children would be "immunised" who were in fact already immune. From what is known of the percentage of Schick-positive reactors in various age-groups in any community it is certain that immunisation course would be greatly enhanced if he were d to supervise all the conditions of health and ene. The question of expense may be crucial the moment. The committee asks for the rt to be read as representing its views of the s which *in normal financial conditions* would ppropriate for dealing with the defects revealed he course of its proceedings. It deprecates emeal treatment by such preliminary measures an be taken without incurring new expenditure. This may mean that no action can be looked for until the economic urge has passed. But no one who reads the report will be content to let matters remain as they are, and public opinion may insist on immediate improvement. At all events local authorities may decide to make fuller use of the powers they have, and should find their task lightened by magistrates who have read the report. Prudent parents will seek medical advice before sending their children to an unknown school.

ANNOTATIONS

AWARD TO PROF. THEOBALD SMITH.

HE Manson medal for tropical medical research, n triennially by the Royal Society of Tropical icine and Hygiene, has this year been awarded Dr. Theobald Smith, director emeritus of the artment of animal pathology of the Rockefeller itute of Medical Research. In association with orne in 1893, Theobald Smith showed that red-er fever in cattle was transmitted by ticks, and he same time demonstrated the passage of infection ugh the ova of one generation of ticks to the next. s discovery proved for the first time that a ozoal parasite of mammals could be disseminated the bite of a blood-sucking arthropod. Probably use Theobald Smith was dealing with a cattle er than a human disease this great event in the ory of medicine received scant recognition, though receded the better known work of Bruce on the smission of sleeping-sickness and that of Ross on aria. Furthermore, in 1893 Manson's hypothesis arding the mosquito transmission of *Filaria crofti* constituted only half the truth, since he ught man was infected via mosquito-contaminated er either by swallowing the escaped microfilariæ hrough their penetrating the skin of man. Indeed, as not until March, 1900, when Low demonstrated rial embryos in the proboscis of infected mosquitoes t to Manson from the younger Bancroft that the e mechanism of their entry during biting was lerstood. It is thus no over-statement of the case say that Theobald Smith was the first to transfer insect transmission theory of protozoal disease m the realms of hypothesis to those of established t. In 1904 Theobald Smith reported anaphylactic nptoms in dogs and rabbits, and in a letter to rlich wrote the original description of the classical aphylactic shock in guinea-pigs, often known as the eobald Smith phenomenon. In 1907 he proved at it was possible to immunise guinea-pigs actively the injection of a balanced mixture of diphtheria xin and antitoxin and two years later suggested ther investigations of the method with a view to ultimate application to human beings, thus antici-ting Behring and Park's work by several years.

The previous recipients of the Manson medal have en Sir David Bruce (1923), Senator Ettore rchiafava (1926), and Sir Ronald Ross (1929).

EREBRO-SPINAL FLUID IN CEREBRAL TUMOUR.

LUMBAR puncture has been followed by death in many cases of cerebral tumour that it is considered many to be an essentially dangerous operation that condition. And this is undoubtedly true less a careful technique is followed. F. Fremont nith[1] from a large experience concludes that when pillœdema is present the dangers of lumbar puncture more than counterbalance the information which is likely to be gained from it. In such cases puncture of one or both lateral ventricles is safer and more useful. When, on the other hand, there is no papillœdema, lumbar puncture is of great value. A fine needle with a manometric attachment is used, and the patient is kept in the horizontal position during and after the puncture. The pressure of the fluid is measured, and the absence of block at the foramen magnum and at the point of the needle is tested first by jugular and then by abdominal compression. Besides the usual examinations for colour, cells, and protein, a more detailed chemical examination may be made with the view of excluding uræmia, but usually only the minimum quantity required for the essential tests should be removed. With these precautions lumbar puncture is not dangerous in itself, and it may be of great service in indicating the presence and the degree of intracranial pressure. But when the patient has been dehydrated by cathartics or by the rectal administration of hypertonic saline, pressure readings are valueless. Normal readings may also be obtained with small tumours in the pituitary region, and with some infiltrating growths of the pons.

Ventricular puncture has a special value in that the fluid drawn from the ventricle on the side of the tumour may be yellow, and often contains appreciably more protein than that from the opposite ventricle. The combination of ventricular with lumbar puncture also has its uses in showing by manometric or colorimetric examination the degree of blockage between these two points on the cerebro-spinal fluid system. A block may be caused by tumour in the posterior fossa, by closure of the foramina round the fourth ventricle, or by a cerebellar pressure cone. While it may not always be possible to distinguish between these, there are cases in which combined puncture has a definite diagnostic value.

In a table attached to his paper, Fremont Smith gives many valuable hints on the differential diagnosis of cerebral tumours from other conditions by such complete examinations of the cerebro-spinal fluid. It would be impossible even to summarise these in a limited space, but they indicate the great number of questions which must be answered before we can make the diagnosis of cerebral tumour in the earlier stages. It is not yet generally recognised that a considerable proportion of patients with cerebral tumour die without having developed papillœdema, and even when this is present it is necessary to exclude other possible causes for it, of which the most important are sinus thrombosis and hydrocephalus. It is probable that ventricular puncture might solve some of the difficulties with which these cases are surrounded, but the difficulties and dangers of the operation are likely to delay its acceptance as a routine measure in obscure cases.

[1] Arch. Neurol. and Psychiat., March, 1932, p. 691.

into negative reactors. Loewenstein's ointment which contains not only toxoid but a killed culture of diphtheria bacilli has been used upon a fairly considerable scale. Three inunctions of this ointment are made. The results, as Ramon and Debré abundantly show, are far inferior to those obtained by the injection of toxoid and may give rise to an entirely false sense of security. It is no good dallying, writes Dudley, with weak or diluted prophylactics if ever active immunisation is to eradicate diphtheria from the population at large. As a first essential, however, there must be effective propaganda and coördinated effort, in order that the public may realise, as it does whenever properly instructed, that at the cost of, at most, trifling discomfort to its children, the nation may rid itself of diphtheria with all the suffering, mortality, and expense which the endemicity of this disease imposes.

MEDICAL ENTRY TO PRIVATE SCHOOLS.

Eighteen months ago Sir Charles Trevelyan, then President of the Board of Education, set up a committee to consider what should be done to secure an adequate education under suitable conditions for children attending private schools. The report[1] as now published covers a wide ground, for the term "private school" is used as a convenient name to cover all schools not in receipt of grants from public funds, and the word "proprietor" for the person or persons responsible for them, though they may be the governing bodies of public schools, while the word "children" is not confined to pupils between 5 and 14. Thus construed the problem concerns some 10,000 schools with 400,000 scholars. A large proportion of these schools are excellent; in a few the conditions are seriously defective. Some of them already are inspected, and the Society of Medical Officers of Health urged on the committee that all private schools should be inspected and supervised at least as regards their premises and the general physical conditions. For the purpose of their evidence this society made special inquiries in selected areas with the following result:

> In about 25 per cent. of the cases investigated the schools were carried on under conditions "which can only be described as bad." The natural lighting of the class-rooms was generally sufficient but the desks were ill arranged in relation to the light. In a high proportion of cases the artificial lighting was defective. The ventilation was generally only that of the rooms in an ordinary dwelling-house, and without cross ventilation more cubic space and floor space per scholar were required. The desks were commonly of an obsolete or unsatisfactory pattern and in some schools forms without back rests were used. The great majority of the small schools paid little attention to the provision of proper cloakrooms and of facilities for drying outdoor garments. The closet accommodation was usually inadequate in comparison with the Board of Education standard and in the smaller schools it was rare to find separate closet accommodation for boys and girls. Facilities for washing were frequently lacking or consisted of a sink in the scullery. In one area two out of 10 schools inspected were seriously overcrowded, one having 34 children in a room 21 ft. by 13 ft., and another having 21 children in a room 14 ft. by 13 ft. In some schools there was no playground, in many others only a small backyard. As delicate children were apt to attend these schools the Society considered that the absence of facilities for open air exercise was particularly regrettable.
>
> In another area a school medical officer who inspected three private schools chosen at random, found one fairly satisfactorily housed. A second containing six children was conducted apparently in a converted cellar, badly lighted and too small and overcrowded with furniture to accommodate the children. The third, established for 25 years, contained 20 children all taught in one bedroom measuring 13 ft. by 13 ft. There was no playground except the road.

The law as it stands gives power under the Education Act to prosecute a parent whose child is not receiving efficient instruction, and under the Public Health Act to secure abatement of nuisances on premises; but the mechanism is cumbersome and ineffective. The committee finds the remedy in a scheme of public supervision based upon inspection; to apply to all private schools with certain specified exceptions. Inspection would cover both the instruction and the premises, including the residential accommodation in boarding-schools, and the scheme would include power to compel the closure of schools failing to comply with the minimum requirements, the question of compliance to be determined ultimately by a court of law. The staff employed would be the ordinary inspectorate of the Board of Education or of the local education authorities. While regular medical inspection of children in private schools should be encouraged in every possible way, the committee does not recommend placing on proprietors a statutory obligation to provide such inspection. Boarding-schools however would be required to state on the registration form and in subsequent annual returns the name of the medical practitioner whose services are available in cases of sickness or injury. The nursing arrangements and the accommodation for such cases would be considered during the inspection of the school and dealt with in the inspector's report.

The report is excellent, but seems to us not to stress sufficiently the part which might be played by medical science. If a bench is asked to order the closure of a school on the ground that the conditions are prejudicial to the health of the children, the magistrates will certainly insist on having the evidence of a medical officer. Yet the report seems to contemplate that all the conditions of health should fall within the purview of the educational inspection. Medical inspection is to be encouraged but not made obligatory. If it were made a condition of registration that a medical practitioner should be attached to every school to supervise the health of the children, a big step forward would have been taken. It is true that official medical inspection might cause difficulties with some parents, but the objection would probably disappear if the examiner were a respected local practitioner, and exemption might be granted to children who brought a simple record of physical condition written out by the family doctor. Boarding-schools are to be required to name the doctor whose services are available in cases of sickness or injury, and the value of iir; if now aspiration be applied to the upper mber, bubbles of air will escape from the lower ., when the aspiration ceases, a corresponding ount of fluid will be drawn into the lower cavity; this process be repeated sufficiently, the cavity l be completely filled. To apply this process the sinuses, the patient lies on the back with head extended so that the chin is vertically over external auditory meatus, two cubic centimetres the fluid are introduced into one nostril and the er firmly closed, while the patient breathes ough the open mouth to raise the palate. Inter- tent suction is then applied for three minutes means of a rubber ball and a closely fitting nozzle, which Dr. Le Mée has added a manometer; the gative pressure should be equal to 180 mm. of rcury. The skiagrams are taken immediately an erect posture, and the method is of value in ealing thickening and abnormalities of the mucous mbrane as well as anatomical aberrations. The enoidal and posterior ethmoidal sinuses are more easily filled by this method but, in any us which is infected, occlusion of the ostium may vent entrance of the fluid; in the opinion of Mée and Bouchet, the non-entry of lipiodol shows it the sinus is severely affected and must be treated gically and, on the other hand, every sinus which mits the entrance of the fluid has a good prospect recovery and should not be submitted to operation, en though the usual rules would appear to indicate it. ey lay great stress on the value of this sign, which would be interesting to see confirmed in other arters. The time of evacuation of a sinus may o be studied by this method; according to these thors, half the liquid has normally disappeared 24 hours, two-thirds by the following day, and trace remains after four days. For treatment ey claim good results from a 1 per cent. solution argyrol; the method is very applicable to children whom the sinuses are small but their ostia large, d it is especially useful in the treatment of the sterior sinuses, which are the more easily reached, contradistinction to other methods by which ese cavities are particularly inaccessible.

---

HYSICAL SIGNS OF BUNDLE-BRANCH BLOCK.

IF there are physical signs of bundle-branch block hich may be elicited by ordinary clinical methods id without the aid of the electrocardiograph, these ill obviously be of value. Attempts have been iade to establish a connexion between this condi- on and certain signs discoverable at or near the ırdiac apex on inspection palpation and ausculta- on, but the relation can hardly yet be considered roved. Dr. Maurice Campbell and Dr. S. S. Suzman i our last issue reported the case of a patient with ypertension, paroxysmal dyspnœa, bundle-branch lock, and gallop rhythm. At a later date both the lock and the gallop rhythm had disappeared. lowever, both block of this type and gallop rhythm re common findings in a heart whose reserve is eriously impaired, and the two signs may occur ndependently of one another. They may arise rom a common cause—namely, the functional nsufficiency of the heart muscle. Moreover, the ommoner form of gallop rhythm is produced by he addition in early diastole of a third heart sound, vhile if bundle block be a cause of gallop rhythm ne would expect the third sound to be located in arly systole. In Campbell and Suzman's case the lectrocardiogram, taken after the disappearance of the characteristic bundle-block curve, presents changes which have been repeatedly observed to precede, and in the event of its disappearance, to succeed bundle-branch block. These consist of a well developed ventricular predominance, with a tall R wave and inverted T wave in lead I. This picture has usually been taken as indicating a severe degree of ventricular predominance, but from its frequent appearance as a stage in the development or recession of bundle-branch block, is considered by some to represent a mild grade of this form of block. J. T. King and D. McEachern [1] are of opinion that bundle-branch block can usually be recognised from physical signs. They find, in a series of 50 cases, a visible and palpable reduplication of the apex-beat in about 80 per cent. and a reduplication of the first sound in about 50 per cent. They have demonstrated a bifid apex-beat by photographing the movements of a straw attached to the apex directly on to a plate —a method which we owe to Parkinson—an electrocardiogram being taken at the same time. These tracings carry conviction, and it may be that with the cultivation of clinical technique a new sign of some value may be elicited by inspection and palpation of the cardiac apex.

MANIPULATIVE SURGERY.

THE medical profession on the whole is broad-minded and does not shrink from acquiring information from any source provided that source can produce scientific evidence for its contentions. The practices of bone-setters have aroused the enthusiasm of certain sections of the public, who are unwearied in twitting medical men for refusing to learn from them. But what the public does not wholly realise is that there exist within the ranks of the profession orthopædic surgeons who make a special and profound study of bone and joint diseases, who are well versed in the presumed mysteries of manipulative treatment and who, on account of their better training, more varied experience, wider outlook, and greater facilities do, in fact, practise bone-setting better and more safely than bone-setters themselves. The reason why, in spite of the existence of orthopædic specialists, unqualified practitioners continue to thrive, is because orthopædic surgery has only comparatively recently become recognised as an important specialty; so that a large proportion of general practitioners have not had the advantage of serving their apprenticeship in the orthopædic department of their teaching hospital during their student days. These practitioners are apt not to recognise cases that would benefit by manipulation, and the patients are obliged to take the treatment in their own hands, when they seek the advice of bone-setters, whose services can be advertised in the lay press in a way that is not open to registered doctors. The remedy for this state of affairs will come only when every student is obliged to serve as dresser in an orthopædic department before being allowed to sit for any qualifying examination. Practitioners who have missed this valuable experience need not, however, remain without expert guidance in this branch of orthopædics. Some seven years ago we had occasion to notice favourably a book on Manipulative Surgery, by Mr. Timbrell Fisher,[2] and on another page of this issue will be found an appreciation of a recent work by Mr. Blundell Bankart on the same subject. Such books are useful, for it is necessary to emphasise more strongly than has hitherto been done that orthopædics as a specialty is concerned not only with the prevention and

THE WHITE BLOOD-CELL COUNT IN THE NEWLY BORN.

THE blood of new-born infants shows a high white cell count, chiefly accounted for by polymorphonuclear cells with a tendency to immaturity. A few days after birth the blood picture changes rapidly to the normal infantile count with a predominance of lymphocytes. Dr. W. Bayer,[1] assistant in Prof. Czerny's clinic in Berlin, has been looking for an explanation of the postnatal leucocytosis. Existing theories include such explanations as concentration of the blood in the first few days of life, the reaction of the organism to extra-uterine life, sudden loss of some regulating factor present in the maternal blood, endocrine disturbances at the time of birth, and the reaction of the infant to some tissue-injury brought about by birth trauma. Bayer examines these theories and finds them mostly inadequate. In his own investigations he first of all carried out a careful series of white cell counts on 20 normal new-born infants and confirmed the accepted view that polymorphonuclear cells amounted to 62 to 65 per cent. of the total white cell count on the first day of extra-uterine life, while by the third to fifth day the lymphocytic percentage had usually crept up to between 50 and 60 per cent. He next studied a series of infants delivered by Cæsarean section, paying special attention to those instances where labour had not begun and where there had been no preliminary interference of any sort. He showed that the white cell counts in this series were identical with those found in babies after normal labour. This fact eliminates several of the theories outlined above. Next he examined 11 infants who during birth showed either hæmorrhage into the skin or cephalhæmatoma or hæmorrhage from the alimentary canal. They all had white cell counts exactly similar, as regards the polymorphonuclear leucocytosis, to those of normal infants. One of the highest percentages of these cells found was in a baby which was asphyxiated at birth. In this case, too, there was a marked "shift to the left" and these facts are significant in view of certain later findings. Bayer proceeded to try to find out what it was that controlled the postnatal development of the white cells and what determined a myelogenous activity immediately before and after birth. A series of animal experiments with various hormones yielded almost uniformly negative results. Endocrine secretions were chosen which might be expected to be present in the maternal blood before birth such as Prolan (anterior pituitary), Unden (ovarian), Progynon (ovarian), placental extracts, and thymus extracts. Experiments on mice showed that the blood picture could not be altered in new-born animals by injecting these hormones either into the mothers or the offspring. Lastly he investigated the influence of carbon dioxide and oxygen on the blood picture and was able to prove that with an increase in the carbon dioxide content of the air breathed animals develop a polymorphonuclear leucocytosis with a "shift to the left" just as in the new-born child. He comes to the conclusion that this explains the phenomenon. He quotes various authorities regarding the oxygen content of the blood of the fœtus or new-born infant, and concludes that a deficiency of oxygen and an increase in the carbon dioxide is constant at this period of life. The fact that the child with asphyxia showed the blood picture in an extreme form bears out his theory.

Dr. Bayer's conclusion opens up many fields for speculation. Is it possible, he asks, in effect, that a chemical stimulus in the blood is the cause of leucocytosis in other conditions? What, for example, is the relationship of blood oxygen and blood carbon dioxide in leukæmia?

OVERCROWDED BIRMINGHAM INSTITUTIONS.

MANY public assistance areas have inherited costly problems from the old boards of guardians, but few of them are so serious as that which faces the great county borough of Birmingham. Infirmaries and mental hospitals lack satisfactory classification of inmates, and several of them are overcrowded. The work of redistribution had been begun by the guardians, but was far from complete when they were superseded. The *city council is, therefore,* called upon to complete this by no means easy task, and according to a comprehensive report by Dr. H. P. Newsholme, the medical officer, it will cost over £192,000. This is an alarming figure just now, even for Birmingham, especially since Dr. Newsholme assures the council that the matter is of immediate importance. Nor is it easy to question such urgency when he points out that in three of the institutions there is a serious degree of overcrowding, and that much inconvenience results from imperfect classification. Pressure upon space is not the only difficulty that has to be removed; the administrative problems involved in a mixture of different classes of patients are, or may be, acute. At Erdington House, for instance, two-thirds of the 1772 inmates are mental patients of different classifications. Only about 10 per cent. are certified as insane, and less than 20 per cent. as mentally deficient. Who is to control such an institution? The mental hospitals committee is entitled only to deal with patients under the Lunacy Acts, and the Mental Deficiency Acts committee only with the deficient. The proposed comprehensive scheme of reclassification would enable every type of inmate to be housed in a more satisfactory way and, with the help of extensions, would bring together in one institution classes of patients now scattered through two or three. Order would thus replace disorder, and administration be simplified. The *report has been approved,* but nothing will actually be done until the committees concerned ask for the authority of the council to spend the money. There is, moreover, another and an important preliminary. Under the Local Government Act of 1929 the proposals must be submitted to the local hospitals council, which may, perhaps, be concerned to find that while the scheme facilitates transfer it provides no accommodation for additional patients.

DISPLACEMENT METHOD IN NASAL SINUSITIS.

THIS method of introducing fluids into the nasal sinuses was elaborated by A.-W. Proetz and, being easy, harmless, and painless, possesses obvious advantages over methods of injection by means of a cannula or trocar. It is used principally to fill the sinuses with lipiodol before skiagraphy, but may also be employed for the introduction of medicaments. Drs. J.-M. Le Mée and M. Bouchet[1] describe its technique and uses from their experience at the Necker-Enfants-Malades Hospital. The physical principle of the method is this: if a test-tube is divided by a narrow constriction into two chambers, and the upper one filled with fluid, the liquid will not penetrate into the lower by reason of its content

THE HUGHLINGS JACKSON MEMORIAL MEDAL.

ON May 19th, the occasion being the annual eting of the Section of Neurology of the Royal ciety of Medicine, a gold medal and an honorarium 100 guineas will be formally presented to Sir arles Sherrington, F.R.S., the Hughlings Jackson turer for 1931. The medal, of which the obverse reproduced here, was designed by Mr. Percy Metcalfe from a photograph published in *Brain* in 1906. The ceremony marks the completion of the task undertaken early last year, on the initiative of Mr. Leslie Paton, of collecting a memorial fund to endow this lectureship, which is held every ree years. Dr. Wilfred Harris became the energetic asurer of the fund, and the required sum of £1200 is collected from 146 subscribers at home and road. Dr. Harris has added to the interest of the remony by preparing a pamphlet in which he gives me account of Jackson and his times, and of the velopment of journals and societies devoted to the udy of neurology. Hughlings Jackson was one of e four original editors of *Brain*, which was started 1875 as an independent journal. Twelve years ter it became the journal of the recently formed eurological Society of London, and the association ntinued until 1907, when this society, which had ready enlarged its title and scope, amalgamated ith others to form the Royal Society of Medicine. *rain* then resumed an independent existence. The ost attractive feature of the pamphlet is the vivid scription of Hughlings Jackson, under whom Dr. arris served as house physician at the National ospital in 1896. "A gentle soul, unbelievably odest, with a fund of quiet humour," Jackson took exercise, nor cared for outdoor sports, but liked tective stories. Many will sympathise with his ply to Jonathan Hutchinson's effort to get him way from one for a walk on a "beautiful day" in inter. "It's a beautiful day by the fire," said ackson, as he settled closer in his easy chair. ackson, who died in 1911, had never published any mprehensive text-book on neurology, but was a rolific writer of essays and papers, some of which ave recently been collected by Dr. James Taylor nto two volumes of "Selected Writings." The ctureship was founded in 1897, when Hughlings ackson himself inaugurated it in an address on the lations of different divisions of the central nervous ystem, which was published in full in THE LANCET 1898, i., 79). It is proper that a lectureship "in onour of the discoverer of cortical epilepsy and its elation to cerebral localisation" should be suitably ndowed, and that the first recipient of the medal should be one who has done so much to elucidate the physiology of the central nervous system.

UGHLINGS JACKSON MEMORIAL MEDAL.

THE MEDICAL ANNUAL.

WITH the 1932 volume[1] the Medical Annual has attained its fiftieth year of issue, and the jubilee number contains a list of contributors, totalling 201, from 1884 to 1932, with their portraits. The Annual was started in London, but two years later was transferred to its present publisher in Bristol and came under the editorship of the late Dr. Percy Wilde, whose vigorous and inquiring mind gave the Annual a spirit of enterprise which it has never since lacked. The present joint editors, Dr. Carey Coombs and Mr. Rendle Short, speak of Wilde's devotion as almost fanatical in its fervour, the production of the Annual offering him an opportunity of service to the medical profession and to humanity which was welcomed both by himself and by Mr. Hartland Wright, a partner in Messrs. John Wright and Sons, who is still living in retirement. The Annual has been generally regarded as a work of reference, although once or twice in its preface has appeared the suggestion, true no doubt but difficult to realise, that the purchaser would do well to read the volume from beginning to end. To make reference easier there have appeared a series of synoptical indexes with special headings for remedies and diseases, giving the practitioner a rapid means of acquainting himself with essential points and to some extent a connected story of the progress of treatment over a period of years. The jubilee volume differs only from its predecessors in being rather larger than usual, due to illustrations, though these have always been a strong feature. There are contributions on veterinary surgery, as the editors believe that both human and veterinary medicine will gain from a wider knowledge of both spheres of work. For practitioners overseas and in rural practice has been inserted some detailed discussion of the causes and treatment of dental pain. In every department of medicine the review of the year's work has been kept up to date. The supplement contains an index of new inventions and preparations, a list of books of the year, and a useful directory of sanatoriums, spas, nursing homes, and other institutions.

THE USE OF MAGGOTS IN INFECTED WOUNDS.

FROM time to time it has been noticed that wounds contaminated with maggots have shown rapid healing. This observation was again made by W. S. Baer during the late war, and ten years later by animal and clinical investigation he attempted to put the use of maggots on a scientific basis as a method of treatment.[2] S. K. Livingston,[3] who formerly worked with Baer, has continued his inquiries, and relates how by means of an incubator he breeds the flies continuously during summer and winter. The eggs are sterilised in perchloride of mercury and alcohol, and are then placed on sterile agar and beef slopes in test-tubes where the maggots hatch out, the latter are also bathed in the antiseptic solution before use. Of 100 cases treated, 90 of which were cases of chronic pyogenic osteomyelitis, 95 per cent. healed. In a second paper Livingston with L. H. Prince[4] describe a series of 200 cases in adults, the correction of deformities, but also with the art and practice of moving joints for therapeutic purposes. Orthopædic surgeons have acquired, in addition to manipulative skill, a training in differential diagnosis founded on a knowledge of general as well as regional pathology, and a patient who seeks help from a qualified man has all the resources of surgery at his disposal should manipulation be deemed unsuitable, or be unsuccessful in effecting a cure.

A ROOM OF ONE'S OWN.

THE London County Council are developing a nursing service which already includes between 9000 and 10,000 women, and is likely to grow even larger in the future. Among the advantages offered to an entrant to this service are that, within its bounds—that is, without loss of pension rights—experience may be gained in practically any branch of nursing, except perhaps private nursing, and that it is a definite policy of the Council to encourage interchange and promotion between various hospitals and departments. Moreover, a uniform scale of salaries has been devised; the hours of work have been reduced to 56 a week day duty, including a period for lectures, and the aim is to reduce them to 54 a week as soon as practicable; and one weekly rest day in seven is assured. In some of the L.C.C. hospitals the trained staff nurse who prefers to live out has an opportunity of doing so, her initial salary of £65 a year, including board while on duty, being supplemented by a living-out allowance of £90; sisters receive an initial salary of £90, including board while on duty, with non-resident allowance of £130. THE LANCET Commission on Nursing recorded evidence that the innovation was regarded as most successful by the authorities, and we learn that 500 of the trained nursing staff now live out. It is patently the aim of the Council to provide a standard of teaching, accommodation, personal freedom, and amenities which compares favourably with that provided at most voluntary hospitals. The immense task of coördinating the practice at seventy-odd hospitals, some of which fell under the administration of the central public health committee of the Council only two years ago, has been tackled with great vigour, and it was inevitable that inequalities should continue to exist for a time. Accommodation has been one of the most difficult problems, since in the interests of the patients and of the nurses themselves it was decided to enlist the services of 500 extra nurses and probationers. An illustrated pamphlet, issued early last year in order to stimulate recruitment, contained the statement that "the L.C.C. nurse has, from her first day as probationer, a comfortably furnished room of her own." It was evidently the intention of the Council that this should be true before the pamphlet was issued, but though 3664 probationers (81 per cent.) do have single rooms, 215 still occupy wooden cubicles, 92 curtain cubicles, and 529 share a bedroom. Following a complaint by a probationer, who left a hospital after only four days, Miss Esther Rickards, F.R.C.S., drew the attention of the Council to the inaccuracy of the pamphlet in this respect, and it has now been withdrawn. The protests from nurses which her action has aroused have been unmerited. At a meeting of the London and National Society for Women's Service held on May 5th to discuss the Final Report of THE LANCET Commission on Nursing, Miss Rickards took an opportunity of disclaiming any intention to do harm to the nursing service of the L.C.C., for which she had a great admiration. The resentment expressed in a letter from the nursing staff of the hospital in question to the chairman of the central public health committee of the L.C.C. is a good example of the attitude of nurses already acclimatised to the aspirations of newcomers, which may sometimes stand in the way of desirable reforms. Some of them, so they say, preferred curtained cubicles to private rooms, were loth to leave them, and so forth. All this, and the fact that the probationer did not remain in the hospital long enough to appreciate the many advantages offered, are irrelevant. The accommodation supplied was not that promised, and the chief lesson to be learnt from the episode is the danger of premature propaganda.

THE VEGETATIVE NERVOUS CENTRES.

THE possible situation of the centres controlling vegetative activities—to which we referred on April 16th—is considered in greater detail by E. A. Spiegel[1] and by J. Beattie.[2] Spiegel indicates the difficulties encountered in attempting experimentally to demonstrate a functional rapport between a given organ and any definite area in the brain. The chief difficulty lies in the fact that visceral, as opposed to somatic, activity is largely independent of central nervous control and is normally a matter of more local reflexes. Consequently, experimental lesions of the afferent or efferent nervous connexions of the viscera rarely produce dramatic changes in function. Even when changes do take place it is not easy to be sure that they are not indirect consequences of altered activity of the endocrine glands. Spiegel also points out that the various vegetative nuclei are by no means sharply distinct from one another. He concedes, however, that the hypothalamics may be divided into two parts, the one controlling the pituitary gland, the other supplying the viscera via the spinal cord. Beattie, on the other hand, is more explicit. He recognised three anatomical subdivisions of the vegetative centre: an anterior or supra-optic nucleus, situated directly above the optic chiasma and bounded in front by the anterior commissure and behind by the pituitary stalk; the intermediate tuber cinereum surrounding like a collar the infundibular recess; and a posterior nucleus spread out over the lateral wall of the third ventricle behind the middle commissure and extending downwards to the mamillary body. Of these nuclei he believes that the posterior controls sympathetic and the anterior parasympathetic activities. In addition to the connexions mentioned above, the nuclei receive afferent fibres from the olfactory areas and the optic thalamus, and send efferent fibres to the intermediate and posterior lobes of the pituitary gland. The close functional relationship between the latter gland and the hypothalamus (the "neuro-hypophyseal mechanism" of Cushing) is also illustrated by the observation of Popa and Fielding[3] that a part of the blood draining the pituitary is diverted, as a "portal" network, to irrigate the adjacent hypothalamus.

The charting of the hypothalamus and the assessment of its rôle in metabolic and visceral activity form a problem of considerable importance. Its solution should entail a coöperation between the neurologist and the "internist" (to borrow a useful American term) which should be to the advantage of both.

SPECIAL ARTICLES

EXPERIMENTALLY PRODUCED MALARIA.

ALTHOUGH malaria is by far the most common disease in the tropics, if not the most widespread pestilence of mankind, it is only during recent years that really accurate knowledge of it, based on controlled experiments, has been obtained. For the fullest account of experimental malignant tertian malaria that has yet appeared we are indebted especially to the efforts of Colonel S. P. James, F.R.S., and his colleagues at Horton Mental Hospital, Epsom. Their latest work was described in a paper by Colonel James, Dr. W. D. Nicol, and Mr. P. G. Shute, read before the Section of Tropical Diseases of the Royal Society of Medicine, on May 5th.

For the treatment of general paralysis it was at first the practice to use strains of the benign tertian or quartan parasite and, on account of the supposed risks, artificial inoculation with *Plasmodium falciparum* was avoided. At Horton, as experience increased and laboratory organisation developed, it became possible, however, to safeguard against these risks, and from August, 1927, malariotherapy with *P. falciparum* was tentatively used for patients who had not greatly benefited from a course induced by one or other of the "benign" parasites. Since no untoward events followed in the first series of cases, the trial was gradually extended to include patients not previously infected with any form of malaria. Although in the first 22 cases there were two fatalities during or shortly after the malarial course, more than 50 have since been treated without a death, so that the death-rate attributable to a malaria course with *P. falciparum* at Horton is only 4 per cent.—i.e., less than half that of treatment with the benign tertian parasite in mental hospitals in England and Wales (10–14 per cent.).

Eight strains of the parasite were used, two from India, three from Rome, one from Sardinia, and two from West Africa. Some patients were infected by blood inoculation, others by the bites of mosquitoes, while two developed the fever some ten days after being injected intravenously with sporozoites from the salivary glands of infected mosquitoes.

The important question is now raised as to whether there is more than one species of the malignant (crescent-forming) parasite, for Colonel James and his colleagues have found within the same species various geographical races which, while not morphologically different, can be recognised as distinct by their clinical virulence, immunological reactions, and other biological properties. The most virulent infections appeared to be those caused by strains from Rome and Sardinia; moreover, it proved possible to reinfect patients with these strains after they had been rendered immune to strains of Indian origin. A still more significant fact is that English *Anopheles maculipennis* could not be infected by Indian strains of *P. falciparum*, whereas it was quite easy to infect them with European strains from Rome and Sardinia.

The actual artificial reproduction of blackwater fever under these experimental conditions must be adjudged a clinical observation of the first importance. Two patients infected with the Rome-Sardinia strains developed blackwater fever, while a third very nearly did so. No occurrence of this sort was noted with the Indian strain. Very conclusive evidence was also obtained that quinine was the exciting cause of the blackwater attacks, and at the same time it was noted that the severity of the repeated relapses preceding the actual attack was to be considered the antecedent cause.

CHARACTERISTICS OF MALIGNANT TERTIAN INFECTION.

The investigations have included an analysis of the temperature curve during each febrile paroxysm, and they confirm the classical observations of Marchiafava and Bignami as to the existence of definite febrile paroxysm giving a characteristic temperature curve generally exceeding 24, and often lasting 36 or 40 hours. Colonel James and Dr. Nicol see no reason to suppose that there is a form of this parasite which completes its asexual cycle in 24 hours, and therefore produces a malignant quotidian type of fever. And in this matter they have had the advantage, not enjoyed by previous workers, of working with patients who have never before been infected with malignant malaria and who have remained under observation continuously for a year or more.

The general course of the disease in malignant malaria is deduced from a study of 25 cases under continuous observation for over a year after the primary attack, so that it has been possible to summarise the differences between this and the benign tertian. The main points of distinction are as follows: Although in most cases of malignant tertian malaria the infection ceases to recrudesce within two months of recovery from the primary attack, it sometimes continues to do so for a longer period; thus the period of recrudescences merges, without a well-defined break, into what is called in benign tertian malaria "the period of relapse." But Colonel James definitely states that, although some of the seven mosquito-infected patients under observation for over a year since their recovery from the primary attack had many recrudescences during the first six months, none subsequently showed a relapse or recurrence such as is common in benign tertian malaria. Malignant tertian malaria also differs in that no apparent difference can be detected between the disease caused by direct blood inoculation and that produced by the bites of infected mosquitoes. Moreover, quinine treatment of the primary attack brings about a permanent cure in less than 20 per cent. of cases of malignant tertian malaria as compared with 50 per cent. for the benign tertian. Clinically, malignant tertian malaria is an acute disease consisting of a severe primary attack followed by several less severe recrudescences at relatively short intervals, and in this respect it differs from the benign tertian which is essentially a chronic disease. The difference is so marked that it can be said definitely that only in the primary attack is there a grave risk of pernicious symptoms; but it must be understood that in this statement blackwater fever is excluded, for this is a manifestation not associated with abundance of parasites and their active sporulation, as are the other pernicious complications. The parasitic infestation is greatest in the primary attack but also diminishes in each recrudescence.

TREATMENT.

The following conditions have been found to influence the therapeutic effect of quinine on the clinical and parasitological course of malaria: the first 100 apparently being those already mentioned. The second 100 cases consisted of chronic infective bone conditions, and healing was obtained in 88 per cent. A third paper, by E. H. Wilson, C. A. Doan, and D. F. Miller,[5] deals with 26 cases of osteomyelitis, in 19 adults and 7 children, and includes one case of acute osteomyelitis; healing was obtained in 22 cases. It must be pointed out that the maggot treatment is preceded by a radical sequestrectomy with the institution of free drainage and the use of vaccine during treatment. The wound is packed for 48 hours after the operation, and then the maggots are introduced; redressing is required every third to fifth day with the introduction of fresh maggots. Unless drainage is free the maggots may be drowned in the pus. As to the mode of action there are said to be various factors—namely, the ingestion of bacteria and necrotic material, stimulation of the outpouring of blood-serum and the production of an "active principle," which can be obtained by grinding live maggots in sterile saline solution and filtering through Berkefeld filters. *Livingston and Prince* use this active principle for dressing when the wound has been cleaned up by maggots; they are now also using this substance combined with vaccine therapy in the treatment of chronic leg ulcers, sinus and mastoid infections, and middle-ear disease.

STRUCTURE OF ATOMIC NUCLEI.

At a meeting of the Royal Society held on April 28th Lord Rutherford gave a masterly review of the physics of the atomic nucleus on which light has recently been thrown by work done under his direction at the Cavendish Laboratories in Cambridge. The picture of an atomic nucleus generally accepted to-day is a massive aggregate or group of alpha particles with a few free electrons and protons. The alpha particle is a helium atom carrying a positive charge, whilst the more familiar electron is the minute unit of negative electricity. The proton is the name given to the nucleus of the hydrogen atom which is a positive charge having a mass of unity in the atomic number scale. The nucleus is surrounded and held together by a barrier of high positive potential which implies an intense field of electrical force. But these simple mechanical concepts are regarded to-day only as useful simplifications for further research. When the model fails to explain all the observed facts, it does not mean that it is forthwith scrapped. The lesson of relativity and wave mechanics has been one of humility. Physicists no longer demand that a theory shall fit everywhere. So long as it holds over even a limited range it is too valuable to abandon. Lord Rutherford emphasised this in his use of the word picture. The barrier of positive potential is so efficient that any particle must have a high velocity in order to penetrate or shatter the atomic nucleus. Conversely any escaping particles, as for example, the alpha and beta radiation of the spontaneously decomposing radio-active elements, must also have a high velocity to penetrate this barrier. In general two lines of attack on the problem of the nucleus may be distinguished. There is first the method of penetrating the nucleus by an atomic projectile. Secondly, there is the study of what comes out, either as particles or as radiation, and the deduction from such *observations* of the nature of the source. Examination of the band spectra of the lighter elements has yielded evidence in the nucleus of what has been termed spin. The experiments involve the analysis of the fine detail in the spectra, and mathematical treatment of the series of frequencies found. In the method of nuclear penetration by rapidly moving particles there *exists one great experimental difficulty* which is inherent in the actual structure of matter. About 12 years ago Lord Rutherford bombarded nitrogen with high speed alpha particles. He obtained definite evidence that when a nitrogen nucleus was hit the atom was disrupted. To obtain this result a very large number of alpha particles was needed, as the number of direct hits was very small compared with the misses. This is due to the open structure of the atom. The nucleus is surrounded by its attendant electrons, which revolve at what is relatively a large distance, so that there is ample room for the flying particle to miss the target of the minute nucleus. The bombardment must therefore be in the nature of a general barrage, since aiming of atomic bullets is out of the question.

In his address Lord Rutherford made a preliminary *announcement of the results obtained* at Cambridge by J. D. Cockcroft and E. T. S. Walton by a new development of this method. The projectiles used were in this case protons, obtained from an electrical discharge through hydrogen and driven by a potential of 200,000 to 800,000 volts. This high positive potential acts on the positive charge of each proton, giving it a velocity of above 10^9 cm. per second. The jet of protons was allowed to fall on a plate of lithium inclined at an angle of 45°, when it was found that alpha particles began to be shot off from the lithium after the velocity exceeded a certain value. The alpha particles were detected by the tiny flash of light produced on striking a screen of willimite. Their number could be ascertained by a form of the Geiger counter. The explanation given of the effect was that each flash represented the explosion of a lithium atom of mass 7 hit by a proton of mass 1, the result being apparently the production of two alpha particles of mass 4. Other elements are now being examined by this method. This is, of course, not the first time the atom has been split, as the original work of Rutherford has the prior claim to that distinction. At the same meeting J. Chadwick described the steps which led him to identify the existence of the neutron, whose particles carry no effective charge, but have a mass of about unity. They are composed, it is believed, of a proton and electron in such close association that no external field is to be detected. A moving neutron does not produce ions as it flies unless a direct hit is registered. The discovery of the projection of the neutron from the atom of beryllium on bombardment is due to Mme. Curie-Joliot and M. Joliot, and has afforded not only new evidence of the nuclear structure, but has given a new experimental weapon for further research. Dr. Chadwick showed the tracks of the atomic disturbances produced by the impact of a neutron, the photographs being obtained by producing the collisions in a gas super-saturated with moisture, when the water condenses on the ions produced and shows as a track of minute droplets. It is a matter for a justifiable national pride that in all this work the Cavendish Laboratories may be said to have set the pace.

Dr. James Collier will deliver the Morison lectures before the Royal College of Physicians of Edinburgh, at 5 P.M., on Monday, Tuesday, and Wednesday, May 23rd to 25th. His subject will be the Pathology and Clinical Features of Some Types of Peripheral Neuritis.

---

[5] Jour. Amer. Med. Assoc., April 2nd, p. 1149.

nd has established a very exacting system of examination and record. His last report points out that diagnosis he has often experienced difficulty ecause of the inadequency or inaccuracy of the istory given on the schedules sent in by the applicants r their guardians. Many of the medical men who ll up the medical part of the schedules have never ad an opportunity of treating the cases in the early tages, and therefore depended on hearsay. Even n expert ophthalmic surgeon may be at a loss to lassify correctly the original state, and primary nd secondary causes which might have reduced an ye, or a pair of eyes, to the state of disorganisation n which they came seeking for blind benefits.

Dr. Mackay has lived through the whole period luring which the treatment of eyesight has passed rom pure empiricism to systematic examination in nstitutions. So far back as 1890, in a public lecture he urged the desirability of inquiring into the physical ondition of every school-child, including the state of the eyes and eyesight. His suggestion appeared at the time somewhat Utopian, and it was not until 1904 that the first systematic examination of the yesight of school-children in Edinburgh was undertaken by his clinical assistant at the request of the nvestigator appointed by the Royal Commission on Physical Training (Scotland). In 1908 the Education (Scotland) Act of that year empowered the Scottish Education Department to require local education authorities to make a medical examination of school-children. The eye clinic of the Edinburgh school board was started in 1912. Still later, the introduction of schemes for maternity and child welfare had assured the early recognition of defective eyesight in very young children. And now the latest development of all has come about by the establishment of clinics, officered by expert ophthalmic surgeons, through whose certificates alone the benefits of the Blind Persons Act, 1920, can be obtained. Dr. Mackay has had a hand in these and other movements, and the Scottish administrators have appreciated to the full the value of his services.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

SUGGESTED TAX ON THE SWEEPSTAKES.

ACCORDING to newspaper reports, in advance of the introduction of the Budget of the Irish Free State, it is expected that the Minister for Finance will make a raid on the sweepstakes. A special tax —some say 5 per cent., others 10 or even 15 per cent.—is to be put on the total receipts for tickets. If one may regard the figures for 1931 as representative, a tax of 5 per cent. on total receipts would bring to the national exchequer some £450,000. It is believed by those interested in the success of the sweepstakes that a tax of this kind—whatever percentage might be fixed—would have a very depressing effect on the sale of tickets. Foreign purchasers, and they have always been the majority, would, it is thought, resent being asked to pay Irish taxes, however willing they may have been to contribute to the relief of Irish charities. It is thought by many that the hospitals would benefit more if the Government were to content themselves with removing the present exemption from income-tax enjoyed by the hospitals in regard to the sums they receive from the sweepstakes, and drop the proposal of a direct tax.

INCOME-TAX ASSESSMENT ON A HOSPITAL.

An important decision was given by the High Court of the Irish Free State (Mr. Justice Sullivan, Mr. Justice Hanna, and Mr. Justice O'Byrne) last week on an appeal taken by the inspector of taxes against a decision of the Special Commissioners of income-tax in a case in which the inspector claimed that the profits arising from private nursing homes attached to a public hospital were liable to income-tax. The superioress of the Mater Misericordiæ Hospital, a public charitable institution, carried on in association with the hospital certain nursing homes in which patients are received for payment. She contended that they constituted an institution, that there was no such institution as the Mater Private Nursing Homes, that the hospital was not carried on on commercial lines, but on lines that rendered it impossible to make a profit; that a charitable institution was exempt from income-tax. The inspector contended that while the public hospital as a charitable institution was exempt, annual profits arose from the carrying on of private nursing homes, and that the superioress was properly chargeable with income-tax upon such annual profits. The Special Commissioners had found that the hospital was carried on as one undertaking, that no line of demarcation could be drawn between the profitable and the non-profitable part of the activities of the hospital, and they concluded that the superioress was not carrying on a trade, and that the assessment should be discharged. The High Court gave judgment in favour of the appellant, the inspector of taxes, and against the superioress of the hospital. The Court held that the Special Commissioners had misdirected themselves in law in holding that the concern was run as an undertaking, and that there was no financial demarcation between the profitables and the unprofitables. The proper question for the Commissioners to determine was whether the superioress did habitually during the tax year let for hire the rooms and beds, with private accommodation, board, nursing, and, in some cases, medical and surgical attendance. If the answer was in the affirmative, then she carried on a trade in the meaning of the Income-tax Acts. The case must be remitted to the Special Commissioners, each party to bear its own costs.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

THE assassination of the President has plunged France into gloom: M. Paul Doumer was a strong calm man, whose wide knowledge of affairs will be particularly missed at this juncture.

SICKNESS INSURANCE AND DEATH-RATES.

Sickness insurance has only just been started in France as a whole. But the Departments recovered from Germany have enjoyed its benefits for about half a century. A comparison between the death-rates in these Departments and those in the rest of France should therefore give a rough idea of the value of such insurance. This task has just been undertaken by Dr. Mosser, of Mulhouse. In the *Revue Philanthropique* for April 15th, he refers to an earlier study in which he showed that in the period 1911–21, the death-rate for Alsace and Lorraine was 156 per 10,000 inhabitants, whereas for the whole of France it was 187. In a more mode and dose of infection, the natural susceptibility and resistance to malaria of the patient, the degree of tolerance or "immunity" to malaria which he has acquired before treatment, the species of parasite, and the virulence of the particular geographical race. The conclusion is reached that the usual clinical practice of administering quinine in malignant tertian malaria may not always be in the best interests of the patient. It is often stated that malignant malaria is easier to treat in hospitals in England than in the tropics, but this is because the fever here represents a recrudescence and not a primary attack, so that the patient has already acquired a certain amount of immunity to this particular infection. The failure of Colonel James and his colleagues to get good results with the "Sinton treatment" (quinine plus alkali) is probably also due to the same cause. From the point of view of economy, the importance of prescribing a separate system for each parasite rather than a standard system applicable to all has become much greater since the discovery of *Plasmodium ovale*. Even in primary infections with this parasite the tendency to spontaneous recovery is so marked that it is hardly ever necessary to give more than two small doses of quinine. The new observations on the individuality of different strains of the same species of parasite introduces a new difficulty in the chemotherapeutic tests. A report of highly successful results with new antimalarial preparations would be valueless, unless it were shown that the cases could not be so successfully cured by a few small doses of quinine. From all the information obtained one is apparently justified in withholding quinine for a short period in order to ascertain by frequent blood examinations and clinical investigations whether the parasitic infestation and signs and symptoms are diminishing "spontaneously" or becoming more pronounced.

Colonel James and Dr. Nicol think that the curative effect of Atebrin[1] is very remarkable and that its discovery marks a new epoch in the therapeutics of malignant tertian malaria. This statement is especially significant when it is understood that the experiments were arranged with the view of eliminating errors in chemotherapeutic trials caused by the influences already described. The first trials were made on four cases of malignant tertian malaria which had continued to relapse for more than six months after their primary attacks, and also on patients who were not cured by quinine treatment during the primary fever. The dose of atebrin was 0·3 g. daily (in tablets) for five days. In only one of the 17 cases treated with atebrin did the remedy fail to effect what appears to be a permanent cure.

The action of atebrin, as has already been stated, seems in many ways to be the reverse of that of plasmoquine, for it appears that atebrin will be of little use as a malaria prophylactic.

It is fitting that an interesting instance of plasmoquine prophylaxis should be recorded in the case of Mr. J. Y. Brown, European inspector of the public health department of Nigeria, who in bringing home to England a batch of *Anopheles gambiæ* heavily infected with the sporozoites of malignant tertian malaria, allowed these insects to feed frequently on his own blood whilst taking 0·06 g. of plasmoquine daily as a prophylactic, and the same dose daily for eight days after the last occasion on which he was bitten. Though the patients injected with the sporozoites developed acute malignant tertian malaria, Mr. Brown has remained in his usual good health for more than three months after the last occasion on which he was bitten.

There is little doubt that the facts recorded above mark an advance in our knowledge of this most intricate subject, and fully justify the pains that Colonel James and his colleagues are taking.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

EDINBURGH HOSPITALS SCHEME.

By 41 votes to 13, the Edinburgh hospitals scheme for paying patients has been approved. It is expected that there will be a revenue of £6000 per annum in respect of the three hospitals concerned—Pilton, Craigleith, and Seafield. The convener of the public health committee indicated that no case would be turned away on account of inability to pay, but if anyone responsible for the patient could pay, he would be required to do so. The amount would depend upon the circumstances of the case and might, for example, be as low as 2*s*. 6*d*. a week. This would not be a profit basis. She quoted many instances outside the poor-law where a charge was made for the services given by the corporation—such as baths, washhouses, bowling-greens, and golf courses. The charge made in these cases was not an economic or commercial charge, and the same thing would hold for the municipal hospitals. The scheme would undoubtedly throw a considerable burden on the rates, and the charge made—except to other local authorities for their patients—would in no sense represent the money value of the services, maintenance, and treatment, which the patients would receive. There was a proposal that treatment should be free all round, but the vote was as above. It is assumed that the scheme is now ready for submission to the Department of Health.

NEUROSYPHILIS.

Before the Edinburgh Medical Chirurgical Society on May 4th Dr. David Lees, assisted by Mr. Robert Lees, gave an analysis of 613 cases of neurosyphilis encountered at the Edinburgh clinic during the 12 years of its work. They represent about 4·6 per cent. of the total of some 14,000 cases treated. The proportions of the different varieties are very striking, the percentages of incidence being as follows. Tabes: males, 55·8; females, 47·9. G.P.I.: males, 19·5; females, 19·5. Tabo-paresis: males, 8·6; females, 2·4. Vascular: males, 5·6; females, 6·5. Meningo-vascular: males, 7·4; females, 6·5. Latent cerebro-spinal syphilis: males, 2; females, 13. Gumma: males, 1·2; females, 0·0. Eighth nerve paralysis: males, 0·0; females, 0·0. Optic atrophy: males, 0·0; females, 4·1. For congenital cases, without distinction of sex, the percentages in the same sequence were 26·6, 31·4, 31·8, 1·9, 10·5, 8·5, 0·9, 12·4, 3·8. Of the total 613 cases, males were 55·6 per cent.; females, 27·6; "congenitals," 17·1.

The most striking features are the high percentage of tabes both in males and in females. Contrary to expectation, the incidence of G.P.I. in this series is the same in females as in males; the ratio usually given is nine males to two females. In congenital syphilis there was a high percentage (12·4) for eighth nerve paralysis. Optic atrophy yielded 4·1 per cent. for females and 3·8 per cent. for congenitals. Discussing the question whether early treatment adversely affected the incidence (later) of neurosyphilis Dr. Lees concluded that it did not.

WORK FOR THE BLIND.

Dr. George Mackay has been for 31 years oculist to the Edinburgh Asylum and School for the Blind

PANEL AND CONTRACT PRACTICE

Another State of Mind.

We recently commented on the state of mind of the insured persons in demanding what they consider to be their rights. It is relevant also to consider the state of mind of the insurance practitioner who has the responsibility of refusing or granting these demands. Practitioners quite justly resent any official action which seems to question their bona fides, and we receive letters objecting to the activities of approved society officials and of the staff of the Ministry of Health. And yet it is the plain duty of the Ministry to see that Act and regulations are properly administered; and in face of the Government Actuary's report and the results of recent investigations by the department, it is not to be wondered at that all means available should be used to ensure control. The big rise in sickness claims is seriously jeopardising the growth of additional benefits and stifling the development of the insurance scheme. That the position was and is still serious is shown by the introduction last week of a Government Bill to amend the rates of sickness and disablement benefit. One proposal is to reduce the sickness benefit of married women from 12*s.* to 10*s.* a week, and the disablement benefit from 7*s.* 6*d.* to 5*s.* The Government Actuary's report on the Bill states that even the reduced benefit rates for women will require an increase in contributions from 8½*d.* to 9*d.* to support them, if claims conform to the average of 1928–30. If the claims can be reduced by 10 per cent. the present contributions will be sufficient. In such circumstances it is essential that the state of mind of the insurance doctor should be the right one if he is to do his duty and further the interests of all his insured patients. Many recent attempts have been made to establish a better understanding between doctors and approved societies, and conferences for this purpose are being held up and down the country. A leading article in the *National Insurance Gazette* for April 30th remarks:—

> "The natural attitude of a doctor to his patient must be one founded on sympathy. We cannot possibly ask or expect the doctor to adopt the attitude of a suspicious detective. . . . But the root question, to us, is this: Do the doctors as a whole yet appreciate, as fully as is desirable, that they are being deceived by a number of their patients? Do they fully understand the proved facts and the unchallengeable statistics? The trade dispute claims, the holiday claims, the married women claims are plain enough. Insured persons are getting certificates of incapacity when they are not incapable of work. . . . We want the doctors, as a body, to be convinced that the proved facts call for their coöperation."

That is the considered view of approved society officials. "Very rarely indeed" the *Gazette* concedes, "is dishonesty the difficulty; the trouble is mistakes, in facts and points of view." This seems reasonable enough. If the insurance scheme is not to suffer lamentably at the hands of some certifiers some change in the point of view may be needed.

Drugs and Their Cost.

Under Article 6 of the consolidated regulations the Minister of Health determines the tariff of drugs supplied by chemists as part of medical benefit under the National Health Insurance scheme. The issue of a new tariff for the period April to September, 1932, gives occasion for comment on some features which may escape attention from their very familiarity.

Part I. deals with the calculation of charges for drugs, preparations, and appliances supplied to insured persons. The main principle of this method is that ingredients are charged at cost price and a dispensary fee is added for each prescription. Practitioners might do well to consider this more carefully than they have done in the past. For example, to order boric lint, oiled cambric, absorbent wool and bandage to a septic focus means a dispensing fee for each article supplied, whilst if the complete dressing is ordered under the title Standard Dressing No. 2 the same materials are supplied with only a single dispensing fee.

Part II. sets out details of dispensing fees, this year subject to a 10 per cent. deduction. It is cheaper when ordering capsules, lozenges, pastilles, tablets, or pills, if two dozen are required to order them at once rather than one dozen to be repeated in say a week's time. Provision is made that, in addition to the fee specified in the scale, actual out-of-pocket expenses are payable in respect of insulin, serums, vaccines, proprietary preparations, and appliances not included in the tariff which need to be obtained specially by the chemist.

Part III. gives the prices of drugs and preparations. Drugs, like other commodities, vary in price. Bismuth, for example, has been lately very expensive, but recently has dropped a little in price. The same applies to the iodides. Many of the chemicals used in dispensing come from abroad and will be subject to the 10 per cent. duty. This may have a substantial effect on the cost of prescriptions generally. It should be noted, however, that last year there was money over, after all the chemists' accounts had been settled, to pay a bonus of just over 15 per cent.

Part IV. contains the official list of appliances. Eye droppers are allowed, but not ear droppers. Eyeshades are not allowed. Hypodermic syringes for diabetic cases, not for asthma. There is doubt as to whether ribbon gauze is allowed. Adrenalin gauze is not in the list, although adrenalin and gauze may be ordered separately. The standard dressings have recently been made up in a more convenient size. No. 1 contains 36 × 12 in. of double cyanide gauze, grs. 180 of absorbent wool, and 1 in. × 3 yds. open wool bandage. No. 2 contains, 1 sq. ft. of boric lint, grs. 240 of cotton-wool, 6 × 6 in. of oiled cambric, and 2 in. × 4 yds. bandage.

Part V. notes the deposits to be made for containers supplied to insured persons, to be paid back when the container is returned in a clean condition. For ordinary medicine bottles over 4 oz. and under 10 oz. the deposit is 2*d.* Some time ago it was proposed that insured persons should be required to bring containers that are graduated, in order to avoid the waste of medicine if (say) 8 oz. of a mixture is placed by the chemist in a beer bottle brought by the insured person; but no regulation has yet been made on the subject.

The drug figures presented to the London Insurance Committees in March were as follows:

	1931.		*1930.*
Total prescriptions for the last quarter	2,145,578	..	2,144,008
Cost of ingredients	£29,539 0*s.* 11*d.*	..	£29,507 17*s.* 7*d.*
Cost of dispensing fees	£39,161 9*s.* 10*d.*	..	£38,984 15*s.* 0*d.*
Total cost of prescriptions ..	£68,700 10*s.* 9*d.*	..	£68,492 12*s.* 7*d.*
Average cost of ingredients ..	3·30*d.*	..	3·31*d.*
Average dispensing fee.. ..	4·38*d.*	..	4·36*d.*
Average total cost of prescriptions	7·68*d.*	..	7·67*d.*
Mean number of persons on lists	1,908,102	..	1,891,058
Average prescriptions per person	1·12	..	1·13
Average total cost per person ..	8·64*d.*	..	8·69*d.*

While the gross figures may appear large the unit figures are small. During the year 1931 chemists on the list dispensed 20,821 prescriptions for insulin at a total cost of £6756 4*s.* 11*d.*

recent study he has found the death-rate for the period 1920–29 to be 143 for the three recovered Departments as compared with 173 for the whole of France. As the latter figure includes the three Departments, the difference between the two must be even greater than the above figures would suggest. In both statistics the Department of the Upper Rhine leads, and the Department of the Lower Rhine comes last, while the Moselle occupies an intermediate position. A comparison of the infant mortality in the recovered Departments with that of the whole of France tells the same tale; in the four-year period 1923–26 the former (Upper Rhine only) was 720 per 10,000 live births, while the latter was 919. In the same period and areas, the death-rates for persons over the age of 1 year were 125 and 157 respectively. Dr. Mosser examines the various factors such as climate, rural and industrial distribution of the population, &c., in the two areas which might possibly explain this consistent and striking difference in the death-rates, and he comes to the conclusion that it is to be found in the benefits of sickness insurance which provides the worker with all the best therapeutic devices of modern medical science and the service of specialists. He calculates that if France, as a whole, could reduce her death-rate to that of the Upper Rhine, there would be a saving of 130,000 lives a year. With the health conscience France is so vigorously cultivating at the present time, there is every prospect of her shortly attaining the goal to which Dr. Mosser points.

MEDICINE AND THE LAW.

Damages for Injured Doctor.

It is the special function of a jury to assess the amount of damages in a common-law action. A new trial will be ordered on the ground of excessive damages only when the amount is greater than any jury would reasonably give—i.e., where the court can find no reasonable proportion between the amount awarded and the loss or injury sustained. In actions for personal injuries due to the defendant's negligence the jury, said Brett, J., in 1873, must not attempt to give damages to the full amount of a perfect compensation for the pecuniary injury, but must take a reasonable view of the case and give what they consider in all the circumstances of the case a fair compensation.

Early this month in Mr. Justice Swift's court a common jury awarded £5243 to Dr. Francis Joyce, of Camberwell-road, S.E., who had been knocked off his bicycle by the defendant's negligence. He received a lacerated wound from elbow to wrist; the ulnar nerve was torn, and the use of his hand in performing surgical operations would be affected. On the day after the trial the defendant's counsel applied for a stay of execution, pending appeal, on the ground that the damages were grossly excessive. Mr. Justice Swift said he did not think the amount was at all excessive in the case of a professional man whose practice depended entirely on his skill with his hands and the appearance which he presented with his hands. The judge refused to stay execution except upon terms that Dr. Joyce should be paid £2500 at once, not to be recoverable in any event, that the balance of £2743 should be paid into court to abide the decision of the Court of Appeal, and that notice of appeal be given and appeal entered within seven days. These terms were, however, varied last Tuesday by order of the Court of Appeal; the sum to be paid forthwith to Dr. Joyce was reduced to £500, the balance to be paid into court within 14 days and costs to be taxed and paid to him on the undertaking to return them if an appeal succeeds. If anybody thinks £5000 a little too much, many may think £500 much too little; it will be interesting to see what principle the appellate tribunal establishes in the event of appeal.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Rear-Admiral W. W. Keir has been appointed to the charge of the R.N. Hospital, Haslar, vice Surg. Rear-Admiral H. C. Whiteside.

The following appts. are notified: Surg. Lt.-Comdr. (D) O. J. Barrable to *Victory*, for R.N. Barracks. Surg. Lts. (D) R. W. Stevens to *Resource*, and J. C. Benson to *Ganges*.

ROYAL ARMY MEDICAL CORPS.

Maj. J. H. Baird retires on retd. pay.

MILITIA.

Maj. J. B. Williamson retires on attaining the age limit and retains the rank of Maj.

TERRITORIAL ARMY.

Maj. G. A. Bridge, R.A.M.C., to be Divl. Adjt., 42nd (E. Lan.) Div. & Sch. of Instn., vice Capt. F. C. Hilton-Serjeant, R.A.M.C., vacated.

I. Mackintosh (late Lt. Malay States Vol. Corps) to be Lt.

ROYAL AIR FORCE.

The undermentioned are granted short service commissions as Flying Officers for three years on the active list: O. S. M. Williams, T. A. Hunt, and H. J. Melville.

Flying Officer V. H. Tompkins ceases to be seconded to the General Infirmary, Leeds.

Squadron Leader R. E. Bell is placed on the retired list at his own request.

Dental Branch.—J. E. Willoughby is granted a non-permanent commission as a Flying Officer.

DEATHS IN THE SERVICES.

Major-General Bruce Morland Skinner, C.B., C.M.G., M.V.O., an old St. George's man who qualified in 1879, died at Colchester, aged 74. He entered the Army Medical Service in 1882, and subsequently served on the North-West Frontier of India (medal with clasp). In the South African war of 1899–1901 he was present at the relief of Kimberley, and at the battles of Paardeberg, Poplar Grove, and Driefontein (despatches, Queen's medal with five clasps). He was made M.V.O. in 1906, and in 1910 was appointed honorary surgeon to the Viceroy of India. For a time he acted as secretary of the Advisory and Nursing Boards at the War Office, and was afterwards Commandant and Director of Studies at the Royal Army Medical College. During the European war (mentioned in despatches five times, C.M.G. and C.B.) he was director, after Deputy Inspector, of Medical Services. He retired in 1917, and in the following year received the honorary rank of major-general.

The name of Maj. H. C. Godding, R.A.M.C., has been brought to notice by His Excellency, General Sir Philip Chetwode, Commander-in-Chief in India, for distinguished services rendered in connexion with military operations on the North-West Frontier of India, during the period October, 1930, to March, 1931.

Donations and Bequests.—Among other bequests the late Mrs. Florence A. Oldham, of Birchington, left by will on the death of her husband £1000 each to the Cancer Hospital, Brompton, and the Royal Hospital for Incurables; and £500 each to St. Thomas's Hospital and Tottenham Cottage Hospital.—The late Mr. Thomas H. Lowthian, of Buxton, left £1000 each to the Devonshire Hospital, Buxton, the Manchester Royal Infirmary, and the Lancashire, Cheshire, and North Wales Council of the British Empire Cancer Campaign; and £500 to the Buxton Cottage Hospital.—By the will of the late Miss Agnes Jane Templeton, of Holme Hill, Dunblane, Perthshire, the following bequests have been made among others: £500 each to the Glasgow Royal Infirmary, Western Infirmary, Glasgow, Victoria Infirmary, Glasgow, and Glasgow Royal Cancer Hospital; £300 to Glasgow Medical Missionary Society.—The late Mr. Godfrey George Halsted, of Poling, in addition to other bequests, left £4000 to Chichester Infirmary.

has since been stated by Heller and Holtz,[1] and also by Jeffcoate,[2] that solutions of crystalline œstrin exert no synergic effect of the kind described. We have also examined the effect of crystalline œstrin (which was not available in 1928), and we wish to state that we confirm Heller and Holtz, and Jeffcoate.

We are, Sir, yours faithfully,
ALECK BOURNE,
J. H. BURN.

London, May 5th, 1932.

UNDULANT FEVER.

To the Editor of THE LANCET.

SIR,—Dr. C. P. Beattie points out in your last issue (p. 1002) that in Scotland the routine examinations of Widal sera reveal a certain number of unsuspected cases of undulant fever. Our experience in this part of Wales is the same. Since 1928 we have added *Br. abortus* to the list of organisms to which we test the agglutinating power of Widal bloods and have found 4 out of 143 gave a titre of 1 in 250 or more. All four bloods proved to be from typical cases of undulant fever. On the other hand, all the others were negative in 1 in 25. We also tested the agglutinating power of 1325 Wassermann sera, and of these 6 gave partial agglutination in 1 in 40 and one agglutinated up to 1 in 50. It is clear therefore that the generally accepted titre of 1 in 100 can be taken as diagnostic. Again our findings regarding average cow's milk are the same as those of Dr. Beattie and others; 76 routine samples of mixed milks were specially examined for *Br. abortus* by my colleague Mr. J. H. Sugden, and of these 28—i.e., 37 per cent.—were shown to be positive by guinea-pig inoculation.

It is significant of the little interest taken in this subject that it is unusual for me to be asked to examine Widal bloods for undulant fever, although the clinical note sent with the specimens seldom points definitely to enteric fever.

I am, Sir, yours faithfully,
WM. PARRY MORGAN.

Institute of Preventive Medicine, Cardiff, May 7th, 1932.

CŒLIAC DISEASE AND DWARFISM.

To the Editor of THE LANCET.

SIR,—Statements by Dr. J. W. Shackle in a letter which you published on May 7th seem to us still further to support our view that the case in dispute was one of idiopathic steatorrhœa with associated bone deformities and a megalocytic anæmia. He now states that he does not regard the case as one of renal dwarfism. In the original description no mention is made of the character of the stools nor of a chemical estimation for the percentage of fats and fatty acids. It is a common experience that patients suffering from idiopathic steatorrhœa may present at times no diarrhœa. Dr. Shackle states that the symptoms "would have needed to be fairly severe to produce the degree of dwarfism that existed." On the contrary in adolescent patients severe cœliac rickets with dwarfism is commonly unassociated with diarrhœa, though indeed the stools are pale and porridgy and contain a large excess of split fats. In such cases the past history of diarrhœa may be obtained only on interviewing the parents, the patient having forgotten its occurrence. The explanation for this lies in the development of dilatation of the colon which may assume considerable proportions.

Concerning the blood picture, cases of Addisonian pernicious anæmia in children have indeed been described, but, so far as we are aware, no associated dwarfism has been recorded though a somewhat similar blood picture may occur with idiopathic steatorrhœa and dwarfism.

A case recorded in 1920 by Dr. H. L. Tidy is quoted by Drs. Hampson and Shackle in their original paper. The blood picture described in this case is quite unlike that found in Addisonian pernicious anæmia, since large numbers of immature white cells were found in the peripheral blood. The picture is, however, similar to that found in erythroblastic anæmia, of which we have studied two cases associated with the other symptoms of idiopathic steatorrhœa. These cases are shortly to be published. Erythroblastic anæmia is characterised by megalocytosis and high variability of the red cells, large numbers of nucleated red cells, and sometimes primitive white cells in the peripheral blood. Its association with bone lesions was first described by Cooley in 1927.[1]

Dr. Tidy himself suggests that the bone lesions in his case were secondary to the disturbances of hæmatopoiesis. In view of modern knowledge it is more likely that the two conditions are dependent upon failure to absorb essential factors, as are the other symptoms of the disease.

We are, Sir, yours faithfully,
JANET M. VAUGHAN,
DONALD HUNTER.

London Hospital, Whitechapel, E., May 9th, 1932.

DEEP X RAYS IN THE TREATMENT OF OSTEO-ARTHRITIS.

To the Editor of THE LANCET.

SIR,—In your leading article (April 30th, p. 941) on the economic aspect of the rheumatic diseases no specific mention was made of deep X rays. This treatment, it is true, has little value in the polyarticular variety of rheumatism, in the ulnar defection of the fingers and constitutional disturbance, generally known in this country as rheumatoid arthritis, but in the case of osteo-arthritis of hyperthymic type which occurs in middle-aged people who otherwise appear to be in good health, the effect of properly applied X ray treatment is often remarkable. Function as well as pain is beneficially affected, and the economic aspect therefore becomes of importance. Moreover, the treatment of osteo-arthritis by X rays can be carried out very largely by making use of existing hospital facilities. I have had personal experience of this work for three years, both in hospital and private practice, but most of my cases have so far been of the hospital type, and, unfortunately, all suffering from an advanced form of the disease with osteophytes and destruction of the intra-articular cartilages.

What can be done for these cases? In ascending order: (1) By the relief of pain the patients become less troublesome in their homes, and their relatives have more time and freer minds to deal with their own work. (2) Function may improve sufficiently for an almost helpless patient to get about the house and attend to himself. (3) A patient who has been able to walk a few hundred yards only may be enabled to return to light employment. (4) In a

CORRESPONDENCE

STERILITY.

To the Editor of THE LANCET.

SIR,—Mr. Victor Bonney's admirable address on Sterility presents the local aspects of the subject which he considers in a very lucid manner. As he says, the more general, namely, the effects of the internal secretions—and, he might have added, of the vitamins, particularly vitamins D and E—are more difficult to assess, but are undoubtedly of great importance. There are, however, one or two points in connexion with the remarks of Mr. Bonney which I should like to supplement.

Mr. Bonney refers to the beneficent effect that has been observed after dilatation of the cervices of relatively sterile nulliparæ, and says that as the cervical canal can never of itself be an obstruction to the ascent of spermatazoa "it is difficult to see how it [dilatation] acts." I think the explanation is this. Such cervices are unlacerated and embrace the dilators tightly; consequently a non-perforated dilator acts as a piston and forces air through the Fallopian tubes. Personally, I have used canalised dilators in order that fragments of endometrium or neoplasms may not be driven through the tubes and become implanted on the peritoneum. This view is supported by the fact that simple transcervical insufflation of the tubes as now practised is not infrequently—more commonly, I think, than Mr. Bonney implies—followed by pregnancy. I entirely agree with what Mr. Bonney says about curettage. For sterility alone it is a vicious practice. Many men seem to have a "D. and C." complex; they cannot dilate the cervix without curetting also. I have seen several cases in which this operation has been followed by infection with blockage of the tubes.

The rest of my observations concern points of technique in regard to remedial measures. First, may I say how pleased I am to find Mr. Bonney a supporter of conservative methods in regard to the Fallopian tubes; and once more I may be allowed to remark that successful conservative surgery is largely dependent on operative skill, and opinions as to its merits are liable to be based on the technical competence of the surgeon concerned. As I was the first to advocate, describe, and illustrate insufflation of the Fallopian tubes from above (Article Disorders of Function in Eden and Lockyer's "System of Gynæcology," 1917) some years before Rubin introduced transcervical insufflation, I may claim to have had a very large experience of it and of reparative tubal operations. I do not believe the type of syringe used matters much, but I do think enough consideration has not been given to the type of point employed. This should be set at an angle to the body of the syringe, for one cannot always in a fat woman "deliver" the tube. The point itself should not be too long; it should be smooth, blunt, and tapering, as is one of those supplied with Gray's syringe for local anæsthesia. An olive-like swelling not far from the point may be an advantage by making for ease in compressing the tubal wall round the point with the thumb and first finger.

I fail entirely to see the advantage of using the sphygmomanometer attached to a metal tube passed through the cervix with the related clamping of the other tube, as advised by Mr. Bonney. As he mentions, it is practically always possible on insufflation to observe the site of obstruction, if any, by the dilatation of the tube behind the point of blockage. When the air passes readily into the uterus it can be heard—even by spectators present—roaring through the cervix; and, as I have often demonstrated, in the absence of any noise, air that has passed into the uterus can be felt gurgling in this organ when it is nipped between the finger and thumb, and expelled.

With regard to salpingostomy, I believe in imitating Nature so far as is possible, and therefore I do not perform a "cuff operation," but slit the tube for half an inch along the antimesenteric border, overturn the edges and bring the mucosal point down to the ovary in order that there may be a gutter-like entrance to the tube in imitation of the ovarian fimbria which I believe to be of importance, although it represents all that is "left" of the so-called hydrocele-envelope enclosing the orifice of the tube and the ovary in the hedgehog and in certain rodents.

Lastly, I do not like Mr. Bonney's method of tubal implantation. Has he found the tubes patent on subsequent transcervical injection with lipiodol? Implantation of the Fallopian tubes is admittedly a very delicate and difficult operation. I think it is absolutely essential that the tube be split at the uterine end, as in the case of the ureter to be implanted in the bladder, and that one flap be fixed to the anterior surface of the endometrium and the other to the posterior surface. Prior to the fixation a Cleveland ligature-forceps should be gently passed through the separated, but already dilated tube and a couple of strands of thin silkworm gut drawn through and allowed to project to the extent of about an inch beyond the abdominal ostium. The other ends should be coiled up and left in the uterine cavity to be withdrawn, with the patient under gas, a week or ten days later. This is easily accomplished if the cervix be slightly dilated and an angled pair of compression forceps be used to seize the threads. Again, it is necessary to ensure by incisions in the uterine wall that the tubes be not compressed as they pass through the uterus.

In spite of these suggestions I do not for one moment wish to imply that finality of technique in these intricate conservative operations has been reached. For this reason I have not written much about details, holding that, provided surgeons recognise the essential principles, the development of the best methods to secure the end desired is not long delayed.

I am, Sir, yours faithfully,

W. BLAIR BELL.

Liverpool, May 8th, 1932.

SYNERGIC ACTION OF ŒSTRIN.

To the Editor of THE LANCET.

SIR,—In THE LANCET in 1928 (ii., 1020) we published a short paper showing that a preparation containing œstrin, when added to a bath containing an isolated uterus taken from a guinea-pig, had the effect of causing the muscle to contract more vigorously when pituitary (posterior lobe) extract was added to the bath; we observed that the preparation of œstrin used did not similarly affect the contractile response to histamine. We stated our opinion that the augmentation of the response to pituitary extract must be due to the œstrin itself, because a non-specific factor, such as protein, would have augmented the response to histamine as well. It has since been stated by Heller and Holtz,[1] and also by Jeffcoate,[2] that solutions of crystalline œstrin exert no synergic effect of the kind described. We have also examined the effect of crystalline œstrin (which was not available in 1928), and we wish to state that we confirm Heller and Holtz, and Jeffcoate.

We are, Sir, yours faithfully,
ALECK BOURNE,
J. H. BURN.
London, May 5th, 1932.

UNDULANT FEVER.

To the Editor of THE LANCET.

SIR,—Dr. C. P. Beattie points out in your last issue (p. 1002) that in Scotland the routine examinations of Widal sera reveal a certain number of unsuspected cases of undulant fever. Our experience in this part of Wales is the same. Since 1928 we have added *Br. abortus* to the list of organisms to which we test the agglutinating power of Widal bloods and have found 4 out of 143 gave a titre of 1 in 250 or more. All four bloods proved to be from typical cases of undulant fever. On the other hand, all the others were negative in 1 in 25. We also tested the agglutinating power of 1325 Wassermann sera, and of these 6 gave partial agglutination in 1 in 40 and one agglutinated up to 1 in 50. It is clear therefore that the generally accepted titre of 1 in 100 can be taken as diagnostic. Again our findings regarding average cow's milk are the same as those of Dr. Beattie and others; 76 routine samples of mixed milks were specially examined for *Br. abortus* by my colleague Mr. J. H. Sugden, and of these 28—i.e., 37 per cent.—were shown to be positive by guinea-pig inoculation.

It is significant of the little interest taken in this subject that it is unusual for me to be asked to examine Widal bloods for undulant fever, although the clinical note sent with the specimens seldom points definitely to enteric fever.

I am, Sir, yours faithfully,
WM. PARRY MORGAN.
Institute of Preventive Medicine, Cardiff, May 7th, 1932.

CŒLIAC DISEASE AND DWARFISM.

To the Editor of THE LANCET.

SIR,—Statements by Dr. J. W. Shackle in a letter which you published on May 7th seem to us still further to support our view that the case in dispute was one of idiopathic steatorrhœa with associated bone deformities and a megalocytic anæmia. He now states that he does not regard the case as one of renal dwarfism. In the original description no mention is made of the character of the stools nor of a chemical estimation for the percentage of fats and fatty acids. It is a common experience that patients suffering from idiopathic steatorrhœa may present at times no diarrhœa. Dr. Shackle states that the symptoms "would have needed to be fairly severe to produce the degree of dwarfism that existed." On the contrary in adolescent patients severe cœliac rickets with dwarfism is commonly unassociated with diarrhœa, though indeed the stools are pale and porridgy and contain a large excess of split fats. In such cases the past history of diarrhœa may be obtained only on interviewing the parents, the patient having forgotten its occurrence. The explanation for this lies in the development of dilatation of the colon which may assume considerable proportions.

Concerning the blood picture, cases of Addisonian pernicious anæmia in children have indeed been described, but, so far as we are aware, no associated dwarfism has been recorded though a somewhat similar blood picture may occur with idiopathic steatorrhœa and dwarfism.

A case recorded in 1920 by Dr. H. L. Tidy is quoted by Drs. Hampson and Shackle in their original paper. The blood picture described in this case is quite unlike that found in Addisonian pernicious anæmia, since large numbers of immature white cells were found in the peripheral blood. The picture is, however, similar to that found in erythroblastic anæmia, of which we have studied two cases associated with the other symptoms of idiopathic steatorrhœa. These cases are shortly to be published. Erythroblastic anæmia is characterised by megalocytosis and high variability of the red cells, large numbers of nucleated red cells, and sometimes primitive white cells in the peripheral blood. Its association with bone lesions was first described by Cooley in 1927.[1]

Dr. Tidy himself suggests that the bone lesions in his case were secondary to the disturbances of hæmatopoiesis. In view of modern knowledge it is more likely that the two conditions are dependent upon failure to absorb essential factors, as are the other symptoms of the disease.

We are, Sir, yours faithfully,
JANET M. VAUGHAN,
DONALD HUNTER.

DEEP X RAYS IN THE TREATMENT OF OSTEO-ARTHRITIS.

To the Editor of THE LANCET.

SIR,—In your leading article (April 30th, p. 941) on the economic aspect of the rheumatic diseases no specific mention was made of deep X rays. This treatment, it is true, has little value in the polyarticular variety of rheumatism, in the ulnar defection of the fingers and constitutional disturbance, generally known in this country as rheumatoid arthritis, but in the case of osteo-arthritis of hyperthymic type which occurs in middle-aged people who otherwise appear to be in good health, the effect of properly applied X ray treatment is often remarkable. Function as well as pain is beneficially affected, and the economic aspect therefore becomes of importance. Moreover, the treatment of osteo-arthritis by X rays can be carried out very largely by making use of existing hospital facilities. I have had personal experience of this work for three years, both in hospital and private practice, but most of my cases have so far been of the hospital type, and, unfortunately, all suffering from an advanced form of the disease with osteophytes and destruction of the intra-articular cartilages.

What can be done for these cases? In ascending order: (1) By the relief of pain the patients become less troublesome in their homes, and their relatives have more time and freer minds to deal with their own work. (2) Function may improve sufficiently for an almost helpless patient to get about the house and attend to himself. (3) A patient who has been able to walk a few hundred yards only may be enabled to return to light employment. (4) In a

CORRESPONDENCE

STERILITY.

To the Editor of THE LANCET.

SIR,—Mr. Victor Bonney's admirable address on Sterility presents the local aspects of the subject which he considers in a very lucid manner. As he says, the more general, namely, the effects of the internal secretions—and, he might have added, of the vitamins, particularly vitamins D and E—are more difficult to assess, but are undoubtedly of great importance. There are, however, one or two points in connexion with the remarks of Mr. Bonney which I should like to supplement.

Mr. Bonney refers to the beneficent effect that has been observed after dilatation of the cervices of relatively sterile nulliparæ, and says that as the cervical canal can never of itself be an obstruction to the ascent of spermatazoa "it is difficult to see how it [dilatation] acts." I think the explanation is this. Such cervices are unlacerated and embrace the dilators tightly; consequently a non-perforated dilator acts as a piston and forces air through the Fallopian tubes. Personally, I have used canalised dilators in order that fragments of endometrium or neoplasms may not be driven through the tubes and become implanted on the peritoneum. This view is supported by the fact that simple transcervical insufflation of the tubes as now practised is not infrequently—more commonly, I think, than Mr. Bonney implies—followed by pregnancy. I entirely agree with what Mr. Bonney says about curettage. For sterility alone it is a vicious practice. Many men seem to have a "D. and C." complex; they cannot dilate the cervix without curetting also. I have seen several cases in which this operation has been followed by infection with blockage of the tubes.

The rest of my observations concern points of technique in regard to remedial measures. First, may I say how pleased I am to find Mr. Bonney a supporter of conservative methods in regard to the Fallopian tubes; and once more I may be allowed to remark that successful conservative surgery is largely dependent on operative skill, and opinions as to its merits are liable to be based on the technical competence of the surgeon concerned. As I was the first to advocate, describe, and illustrate insufflation of the Fallopian tubes from above (Article Disorders of Function in Eden and Lockyer's "System of Gynæcology," 1917) some years before Rubin introduced transcervical insufflation, I may claim to have had a very large experience of it and of reparative tubal operations. I do not believe the type of syringe used matters much, but I do think enough consideration has not been given to the type of point employed. This should be set at an angle to the body of the syringe, for one cannot always in a fat woman "deliver" the tube. The point itself should not be too long; it should be smooth, blunt, and tapering, as is one of those supplied with Gray's syringe for local anæsthesia. An olive-like swelling not far from the point may be an advantage by making for ease in compressing the tubal wall round the point with the thumb and first finger.

I fail entirely to see the advantage of using the sphygmomanometer attached to a metal tube passed through the cervix with the related clamping of the other tube, as advised by Mr. Bonney. As he mentions, it is practically always possible on insufflation to observe the site of obstruction, if any, by the dilatation of the tube behind the point of blockage. When the air passes readily into the uterus it can be heard—even by spectators present—roaring through the cervix; and, as I have often demonstrated, in the absence of any noise, air that has passed into the uterus can be felt gurgling in this organ when it is nipped between the finger and thumb, and expelled.

With regard to salpingostomy, I believe in imitating Nature so far as is possible, and therefore I do not perform a "cuff operation," but slit the tube for half an inch along the antimesenteric border, overturn the edges and bring the mucosal point down to the ovary in order that there may be a gutter-like entrance to the tube in imitation of the ovarian fimbria which I believe to be of importance, although it represents all that is "left" of the so-called hydrocele-envelope enclosing the orifice of the tube and the ovary in the hedgehog and in certain rodents.

Lastly, I do not like Mr. Bonney's method of tubal implantation. Has he found the tubes patent on subsequent transcervical injection with lipiodol? Implantation of the Fallopian tubes is admittedly a very delicate and difficult operation. SYNERGIC ACTION OF ŒSTRIN.

To the Editor of THE LANCET.

SIR,—In THE LANCET in 1928 (ii., 1020) we published a short paper showing that a preparation containing œstrin, when added to a bath containing an isolated uterus taken from a guinea-pig, had the effect of causing the muscle to contract more vigorously when pituitary (posterior lobe) extract was added to the bath; we observed that the preparation of œstrin used did not similarly affect the contractile response to histamine. We stated our opinion that the augmentation of the response to pituitary extract must be due to the œstrin itself, because a non-specific factor, such as protein, would have augmented the response to histamine as well. It

OBITUARY

SIR THOMAS MORISON LEGGE, C.B.E., M.D. Oxf., D.P.H.,

LATE SENIOR MEDICAL INSPECTOR OF FACTORIES.

WE regret to announce the death of Sir Thomas Legge, which occurred on Saturday, May 7th, at Wintergreen, Warlingham, in the 70th year of his age.

Thomas Morison Legge was born at Hong-Kong in 1863, the younger son of Prof. James Legge, the well-known Chinese scholar. He was educated first at Dollar Academy, of which he always preserved happy memories; but when his father was appointed Professor of Chinese at Oxford he was entered at Magdalen College School. He proceeded to Trinity College, Oxford, and completed his medical education at St. Bartholomew's Hospital. He graduated as M.B., B.Ch. Oxf. in 1890, and obtained the doctorate in 1894. He was brought up in an academic atmosphere which affected his whole life. He read physiology under Burdon Sanderson and Gotch at a time when J. S. Haldane and Leonard Hill were working in the laboratories, and obtained honours in the natural science school. Interested from the first in problems of public health he was fortunate in being able to make a long stay on the Continent investigating them. He paid a series of visits to Paris, Berlin, Brussels, Copenhagen, Stockholm, and Christiania (now Oslo), and in 1896 wrote a useful book, entitled "Public Health in European Capitals," describing the municipal sanitary administration in those cities. As a result mainly of the discriminating qualities of this work, he was appointed secretary of the Royal Commission on Tuberculosis which sat during 1896–98, and his familiarity with the foreign centres was most valuable to the Commissioners on their personal tours of inspection. On the conclusion of the labours associated with the Commission he worked for a short time under Sir Arthur Newsholme, then M.O.H. for Brighton, and was soon appointed the first Medical Inspector of Factories and Workshops, a post which he held for nearly 30 years. He was associated from the beginning with Sir Arthur Whitelegge, who had recently been brought from Yorkshire to be Chief Inspector of Factories, the appointment not being associated with his medical qualification. Legge threw himself with zest into the work. A description of that work was given modestly in the Shaw Lectures which he delivered before the Society of Arts in 1929, when he set out 30 years' experience of industrial maladies. In one of these lectures he described as the most exciting day of his life that on which he was able to connect posterior cortical cataract with the exposure to glare in a glass-blowing factory, confirming the observations of a half-blind trade-union official. An investigation into the existence of cataract among the members of certain large trade-union societies followed and confirmed Legge's findings. In the same Lectures he resumed his share in clearing up the causation of nystagmus and described inquiries into trinitrotoluene poisoning, grindstone silicosis, and many conditions, such as "beat-hand," "beat-elbow," and "beat-knee," which bulk largely in questions of compensation. The main message of these addresses was that the public were not cognizant of the conditions that existed, and in his Chadwick Lecture, delivered before the Institute of Hygiene, he developed the theme by insisting that his own profession, speaking generally, was little better informed. For he urged the necessity of teaching industrial hygiene to the medical student, regarding such subjects as vital statistics, factory hygiene, and industrial poisoning as barely dealt with in the medical curriculum, so that the duties of the practitioner in respect of preventive medicine and the sanitary administration of the country were left for the young doctor to find out for himself. He held that the medical student should receive a picture of the causes underlying industrial unrest, pointing out that the psychology of the worker and of the employer formed matters of first importance to the country. The theme was always a favourite one with him.

SIR THOMAS LEGGE.

Legge was recognised as one of the first authorities on anthrax in the country, and on this subject he delivered the Milroy Lectures before the Royal College of Physicians of London. Here he detailed the whole story of anthrax in relation to hides, skin, and horsehair, going elaborately into the arguments for and against certain lines of treatment of the human subject. The lectures were published in THE LANCET and the second of them contains a striking analysis of a series of cases of external anthrax treated by Sclavo's serum, when Legge came to the conclusion that with the use of the serum some sufferers were saved, and that internally it was the only treatment holding any hope of benefit. The subject of lead poisoning was also one which Legge made his own in respect of public health aspects. He instituted through his department wide and close inquiries into the amount of injury caused to the workers, and it became common knowledge to the public that for some years there had been a serious annual death-rate from plumbism. The Lead Paint (Protection Against Poisoning) Act followed, and in 1921, under the auspices of the International Labour Office of the League of Nations, with whose activities Legge was always in close relation, a draft Convention was agreed to by the representatives of 30 countries, including Great Britain, having for its object international measures against the disease. Under this Convention the use of lead paint for work was to be made prohibitive, but in 1927 in this country the restriction was not made absolute, only a regulation for the employment of the paint being required. Legge, who was a delegate of the British Government when the Convention had been agreed upon, resigned his position under the Home Office in protest; his convictions enjoined the course upon him, but fortunately his term of office had nearly expired.

In 1918 Legge had received the C.B.E. and in 1925 he was knighted. In addition to his valuable public deliveries, and his book already mentioned, Legge small but by no means negligible proportion of cases the patient's earning capacity may be fully restored.

Why should we allow patients to reach a state of crippledom? Early diagnosis, followed by radiotherapy and other suitable measures, would surely for the most part arrest organic change and prevent loss of function.

I am, Sir, yours faithfully,
F. HERNAMAN-JOHNSON.
Brook-street, W., May 9th, 1932.

THE EXPERT WITNESS.

To the Editor of THE LANCET.

SIR,—Facetious observations dovetailed into a serious discussion are proverbially dangerous. My remark concerning what expert witnesses think of each other, is a case in point (see THE LANCET of last week, p. 990). As the cold print of your excellent report may lead the reader to think I was serious, I venture to claim your hospitality to explain that the remark was intended to be jocular. Luckily the audience, which comprised several distinguished experts, understood—perhaps because I added the well-worn story about the Judges' address to Queen Victoria ("Conscious as we are of our imperfections, &c."). It is common knowledge that, however much experts may disagree in the witness-box, they usually have a generous appreciation of each other's qualities.

I am, Sir, yours faithfully,
20, Queen Anne's-gate, S.W., May 9th, 1932. RIDDELL.

R.C.S. COUNCIL ELECTION.

To the Editor of THE LANCET.

SIR,—Fellows of the Royal College of Surgeons have recently received two documents concerning the impending election to Membership of the Council.

The first of these documents was an appeal signed by members of the Court of Examiners and printed on paper bearing the address of the Examination Hall. It requested Fellows of the College to record their votes in favour of a Member of the Court. This document conveyed to many Fellows the impression of being of an official character, authorised or allowed by the ruling body of the College. It betrayed junior Fellows of the College, who had little experience of exercising their vote, into acting as the document requested. But the second missive showed how mistaken was the view that the first was official. For this document conveyed the terms of a resolution passed by the Council reproving the Court for its improper action which was strongly deprecated.

The difficulty which now confronts many of us in reference to what we regarded as an official request (now known to be a most reprehensible action) is that we have recorded our votes in a manner which, but for the pseudo-official action, we should never have contemplated. The counting of the vote may therefore record a result which we do not desire.

In view of this difficult position may I, on behalf of many friends as well as myself respectfully suggest to the Council that this election be regarded as invalid: or, if that is not possible, that the candidate concerned should consider his action? He would probably not desire to be elected by votes he has not himself earned; by votes, that is, mistakenly given in the belief that we were supporting the desires of a President and Council whom all of us regard with utmost respect, and whose wishes we should desire to observe.

I am, Sir, yours faithfully,
F.R.C.S.
May 6th, 1932.

TRAINING IN TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—In your issue of April 30th (p. 954) Dr. Maurice Davidson makes the statement that there are "only four centres—viz., Manchester, Sheffield, Edinburgh, and Glasgow—at which the existing course of teaching in this subject forms a compulsory part of the curriculum for undergraduates. Instruction in other schools may be admirable, but attendance on the courses is voluntary." He adds: "In centres where no such facilities are offered in the teaching hospital itself, but where ample clinical material and organisation exists in the municipality, there is a lack of adequate coöperation between the medical school and the municipal authorities." So far as the University of Aberdeen is concerned these statements are contrary to the facts. Training in tuberculosis is a compulsory part of the curriculum of candidates for the degress of M.B., Ch.B. of Aberdeen, and has been so for a number of years. In Aberdeen, the university, the voluntary hospitals, and the town council coöperate in the closest and most friendly manner. The lecturer in tuberculosis in the university is also tuberculosis officer for the town council. The head of the public health department in the university is medical officer of the town council as were his two predecessors.

I am, Sir, yours faithfully,
H. J. BUTCHART,
May 6th, 1932. Secretary, Marischal College, Aberdeen.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 30TH, 1932.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 62 (last week 96); scarlet fever, 1669; diphtheria, 813; enteric fever, 22; acute pneumonia (primary or influenzal), 947; puerperal fever, 38; puerperal pyrexia, 106; cerebro-spinal fever, 56; acute poliomyelitis, 3; acute pôlio-encephalitis, 4; encephalitis lethargica, 12; dysentery, 15; ophthalmia neonatorum, 115. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 3rd–4th was as follows: Small-pox, 106 under treatment, 2 under observation (last week 128 and 3 respectively); scarlet fever, 1479; diphtheria, 1308; enteric fever, 8; measles, 2632; whooping-cough, 423; puerperal fever, 14 (plus 6 babies); encephalitis lethargica, 224; poliomyelitis, 4; "other diseases," 99. At St. Margaret's Hospital there were 17 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was no death from small-pox, 1 (1) from enteric fever, 94 (46) from measles, 4 (1) from scarlet fever, 54 (12) from whooping-cough, 25 (2) from diphtheria, 47 (12) from diarrhœa and enteritis under two years, and 72 (4) from influenza. The figures in parentheses are those for London itself.

Liverpool reported 19 deaths from measles, Manchester 3, Bradford and Leeds each 2. Liverpool also reported 6 deaths from whooping-cough, Bristol and Walsall each 3. Diphtheria was credited with 4 deaths at Manchester, 3 at Hull, 2 at Leeds.

The number of stillbirths notified during the week was 300 (corresponding to a rate of 42 per 1000 births), including 49 in London.

MANCHESTER STUDENTS' COLLECTION.—The amount collected by students of the University of Manchester at their Shrovetide rag this year was £4250, or over £1750 less than last year. The sum of £1000 has been allocated to the Royal Infirmary, and the remainder to other medical charities in Manchester and Salford.

JOHN ABERNETHY WILLETT, M.D. Oxf., M.R.C.P. Lond.

We regret to announce the death of Dr. J. A. Willett, which occurred on Thursday, May 5th, in a nursing home in London, in his sixtieth year.

John Abernethy Willett was the second of the five sons of Mr. Alfred Willett, the distinguished surgeon of St. Bartholomew's Hospital, his mother being the only daughter of Sir George Burrows, President of the Royal College of Physicians of London 1871/75. John Willett was educated at Westminster and at Oxford, and proceeded for his medical education to St. Bartholomew's Hospital. He obtained the double English qualifications in 1899, and in the next year graduated in medicine at Oxford, taking the M.R.C.P. Lond. three years later, and in 1906 passing to the M.D. degree. He held the usual resident appointments at St. Bartholomew's Hospital where, afterwards, he was chief assistant in the gynæcological and obstetrical department, and demonstrator of practical obstetrics in the school. Though failing to secure a place on the staff of his hospital he made a fine impression on his colleagues by the character of his work and the standard of his teaching. He was for a period resident medical officer at Queen Charlotte's Lying-in Hospital, and was shortly afterwards elected assistant physician to the City of London Lying-in Hospital and surgeon to the Samaritan Free Hospital. These latter appointments he was holding when he died, although he had just sent in his resignation to both of them, being in each case senior member of the staff. He was also gynæcologist to St. Andrew's Hospital, Dollis Hill.

The contribution to obstetrics by which Willett will best be known is his paper published in 1925 on the treatment of placenta prævia by continuous weight traction. This method was based on a very simple conception and, used in suitable cases, its great simplicity and ease of performance have real advantage over more complicated measures. The results of the use of Willett's forceps in this serious obstetrical condition have been good and have led to an increasing resort to this method of treatment. Both on the staff of the Samaritan Hospital and at the London Maternity Hospital he earned the particular gratitude of the nursing staffs for he was deeply interested in their share of the work and spared no trouble in making both the scientific and practical sides of nursing accessible to them.

Joe Willett, as he was generally known in his own small and intimate circle, was a very simple man, both in his professional and his ordinary life. He was not ambitious in the usual sense of the word and did not strive for public fame or consciously seek the approbation of his fellows. So simple was his life-plan that it seemed as if, early in his career, he had recognised his scope and had made up his mind not to go outside it. Within this scope, he was admirable in all he did and said, and was recognised as an absolutely trustworthy man whose views were sound. The possession of a private income sufficient for his needs enabled him to lead a quiet life (he even kept his name out of the Telephone Directory) and to avoid the fever and the fret of private practice. His pleasures and pursuits were just what would be expected: fishing, good music, and golf—but all enjoyed in a moderate and simple manner. Willett was a sound clinician and a born teacher, and these were the parts of his work which especially appealed to him. He gave of his best to the hospitals he served and the pupils he taught; medical students and post-graduates, midwives and nurses. There was nothing he enjoyed more than giving bedside instruction in the hospital or at the antenatal clinic. Though the reasons could be easily understood, it was a constant source of wonder and regret that with his instinct for clinical teaching he had never attained a position on the staff of a teaching hospital. In place of it, he threw himself wholeheartedly into the teaching of midwives and helped the Midwives Institute as a lecturer, on its advisory committee, and in organising courses of training and examination for the Midwife-Teachers' Certificate. When the Central Midwives Board took over this examination last year, his advice and his experience as an examiner were invoked by the board.

It may be asked whether one who wrote so little and spoke so seldom at medical societies exerted any influence on current obstetric thought? He did, in a quiet way, and almost entirely by personal contact with his colleagues and pupils. His outlook was not so much conservative as limited; and the limitation of his activities was imposed by a natural diffidence and an inborn dislike of competition with other men and other opinions. Willett will be missed by many friends who loved him for his simple character and his loyalty to high ideals of conduct.

ROYAL MEDICAL BENEVOLENT FUND.

AT a recent meeting the committee voted 55 grants, amounting to £997. The following are particulars of a few cases helped:—

Daughter, aged 85, of M.D. Father died in 1869 at the age of 79. The applicant, even at the age of 85, is still trying to maintain herself by her own efforts. She is assistant organist at the parish church, and also teaches music to children, and by these means earns £22 10*s.* She lives in her own small house; she takes in one lodger, who pays £27 a year. Up till recently she let three rooms in her house, but the tenant died last year, and the applicant has been unable to re-let. It was discovered that this old lady's total income was £76 16*s.*, out of which she had to pay rates of £12 13*s.* Fund voted £26 in four instalments for a period of one year, to be renewed annually if circumstances remain the same.

M.R.C.S., aged 56. Had a stroke in the autumn of 1931, and is incapacitated for professional duties. His practice was small, and very little is expected from it. Private income of applicant and his wife, aged 59, does not exceed £50 a year. Fund voted £10, payable in four instalments over a period of one year.

Widow, aged 59, of M.R.C.S., was left penniless by the death of her husband in 1925. At first the applicant took a house and maintained herself by taking paying guests. Afterwards she took a post as housekeeper, which she retained for some years until her health broke down. She has now had to undergo a severe abdominal operation, and a medical report states that she will not be fit for remunerative work in the future.

The applicant therefore becomes entirely dependent on her two daughters, ages 30 and 22, each of whom has employment, but with small salaries. Fund voted £26, payable in four instalments over a period of one year.

Cheques should be made payable to the hon. treasurer of the Fund, 11, Chandos-street, Cavendish-square, London, W.1.

West End Hospital for Nervous Diseases.—Last year there were 522 new in-patients, a small reduction; there was also a fall in the number of out-patients, whose 41,256 attendances nevertheless showed an increase. The average weekly in-patient cost was £3 0*s.* 11*d.*, a reduction of 6*s.* 6*d.* The facilities for adult patients to engage in handicraft under trained instruction have been so satisfactory that they have been extended to the children. The honorary surgeons now have the first call on the beds in two of the single-bed wards.

Fewer Rheumatic Patients at Bath.—The report for 1931 of Bath Mineral Water Hospital records a fall in the number of patients admitted from 1353 in the previous year to 1235; the stay rose from 39 to 41 days. The reduction is attributed in the main to "the determined effort that is being made to treat rheumatic disease not only at the recognised spas, but also at such an important centre as the Red Cross Clinic in London." The new diathermy apparatus at the hospital has had to be doubled, and a room has been arranged and apparatus provided for the examination of throats.

translated and edited Rambousek's "Industrial Poisoning" and also wrote, in collaboration with Sir Kenneth Goadby, a work on Lead Poisoning and Lead Absorption. He lectured on industrial poisons in the London School of Hygiene and Tropical Medicine. He wrote in 1911 a short series of papers on medicine in Scandinavia for THE LANCET, which showed that the training and educational regulations in Sweden, Norway, and Denmark compared in many respects favourably with out own; he delivered the William Withering Memorial Lecture on Hygiene at Birmingham, and made many communications to scientific papers upon industrial disease, and public health; and received from the Royal College of Physicians of London the Bisset Hawkins Medal as an outstanding promoter of public health.

Prof. E. L. Collis writes: "Legge threw himself with enthusiasm into his duties, and rapidly became recognised as a leading authority on diseases of occupation. The work gave him scope to combine knowledge gathered from the past with facts observed in modern industries; for it was thus his training taught him to proceed. New data were reviewed in the light of past history; but the past was always suspect—something open to correction when it did not stand up to the acid test of newly acquired facts. As Milroy lecturer in 1906 he dealt with industrial anthrax; but his name must always be more closely associated with occupational lead poisoning. In this connexion he discovered that the main portal of entry of the poison into the body was by the lungs; he noted, in a masterly way, how the poisoning occurred in this industry and in that, not in accordance with the amount of manual contact with the metal, but in relation to the presence of dust arising from such lead compounds as were soluble in the body fluids. Upon this foundation has been built up the modern methods for preventing the generation of dust or for removing it by exhaust draughts, which have been so successful in controlling plumbism. To-day this old-time scourge has lost most of its terrors; in 1900 over 1000 cases were notified; to-day year after year fewer than 300 cases occur, notwithstanding trade expansion which has spread the risk and the influence of subsequent compensation Acts in bringing cases to light. Many to-day are the codes of regulations on the statute-book aimed at the control of this and other industrial diseases, for which he was responsible. Legge, if a disease could be prevented, held strongly and conscientiously that it must be prevented. Hence, finally, he retired earlier than he need have done from his post, because he disagreed with the provisions of the Lead Paint Act which permits the continued use of lead paints—a trade custom he held to be unnecessary and definitely dangerous. But he did not retire merely to rest on his well-earned laurels, for he had been knighted several years earlier; he turned now to extend a still helpful hand to the working man for whom he had already done so much, and became expert adviser to the Trades Union Council. During the quarter of a century he was a civil servant, Legge was member of a number of Government committees and placed his skilled knowledge before many more. Well known at home, his status was equally recognised abroad, not only in the United States and Canada where he made a lecturing tour, but also in Europe where he represented the Home Office at many international conferences.

"As a colleague, he was an ever helpful friend, always ready to consider a fresh viewpoint. His character was retiring, rather than forceful; but he never spared himself where he considered duty lay. The paths of honour and uprightness were simple for Legge to tread; he knew no others. As a young man he was a fine swimmer and skater, and was always physically active; but his life's hobby was the study of sixteenth century stained glass upon which he was an accepted authority. Here again he combined admiration for bygone art and workmanship with an appreciation of modern skill as portrayed in the windows after Burne Jones and others. This artistic side of the man came out also in his everyday work as he visited factories and saw human activity; for he maintained that grace and beauty were seen at their best as exemplified by man at work; the smith at his forge, road menders swinging sledge hammers, an anvil maker, or a coal heaver, called forth admiration while he would pause a moment to watch. He saw beauty in factory girls in their overalls, rather than among popular stage favourites. Much did he get from life, and much did he give back to his generation."

Dr. John C. Bridge writes: "The death of Sir Thomas Legge removes a pioneer of industrial medicine. To his colleagues he was never Sir Thomas, but 'Tommy.' A personality reserved to shyness and to those who did not know him perhaps apparently rude, but to us who worked with him and for him, a loyal and helpful colleague and chief. It was always interesting to go to him hoping to tell him something new and to hear him say, 'I remember in such and such a year' and then would follow a little lecture on the subject. One always felt that Legge had missed his vocation, he seemed so much better fitted for a more secluded life. An enthusiast is not always practical and Legge was an enthusiast. Sometimes one felt he did not appreciate the work one did; but though he had little use for words of thanks, he never failed to recognise and give full acknowledgement to the work of others. I remember so well saying to him one day after reading an article, 'But that is exactly what you told him (the writer), you ought to write and tell him so.' The reply was, 'So long as the facts are known, it does not really matter who makes them known. Does it?' That was the Legge we who worked with him knew—never jealous of those who learnt from his experience, and always ready to encourage the genuine worker. Industrial medicine was not his only subject of interest, and in art, music, and literature he might have become recognised as an expert, and he was an authority upon stained glass. Nothing pleased him better, after his day's work in some manufacturing town was done than to set out to paint a typical industrial scene. Industrial workers throughout the world owe much to Legge. The reduction of cases of lead poisoning in the pottery industry in this country alone is a memorial of which any man might be proud and this is due mainly to Legge's work. Generous to a degree in giving from his store of knowledge he had only these objects in view—to better conditions for the workers and to further the study of the subject to which he had devoted his life. One great regret is that he did not, when he retired from official life, set himself to write from his great experience all he knew of industrial disease. In choosing otherwise I know he felt he was learning his subject from another aspect."

Sir Thomas Legge married Norah, daughter of Mr. J. Mack, of West Grinstead, and is survived by his widow, two sons, and a daughter.

record of loss of life and often desperate injury on the highways of this country. The total figures of this ghastly record were not the end of the story. Those figures conveyed the fact that this tragedy spread far beyond its immediate surroundings to the relatives and dependants of the victims. Fortunately, public opinion, which was one of the strongest forces that could be brought to bear on this problem was now being awakened. Many advocated as the only solution of this tragic problem new legislation involving the imposition of still more severe penalties on the careless and dangerous driver. Whether such action might eventually prove to be necessary was not for him to say, but there was in their hands a most effective weapon and one which could be immediately applied—namely, the more proper observance of the law and the more rigorous enforcement of the penalties for which it provided.

THE HOSPITAL PROBLEM.

Mr. PARKINSON said that last year after the passing of the Road Traffic Act the number of accidents was considerably less, but there seemed to be a renewal of these accidents. The question of people who were injured and taken to hospitals was becoming a burning cry from every hospital in the country. It was a matter which the Minister should consider. The right hon. gentleman had great powers and he hoped he would exercise them in the interests of national safety and make the Road Traffic Act a really effective measure.

Mr. TINKER said he had had figures given to him in regard to the treatment of injured people in hospitals and the cost last year was put at more than £300.000. Hospitals complained that they were not getting anything like a fair return. He had had a letter from a hospital in his own constituency. The hospital was not a large one. Last year it cost that institution £694 to deal with accidents caused by motorists. He thought that the Road Traffic Act would go a long way towards providing a solution of this question, but this letter stated that the hospital had just received £100, or about one-seventh of the total cost of dealing with these accidents. He was wondering if the Minister of Transport was doing anything to strengthen the Act in this particular. The matter was important not only in his constituency but all over the country.

Mr. BEAUMONT said that the burden of road accidents on hospitals was a difficult problem and many of the suggested solutions were for various reasons impossible, but unless something was done to ensure that hospitals got some remuneration for the accident cases which they had to treat a great number of the smaller hospitals would have to close their doors. He asked the Minister to explore every avenue to see whether anything could be done to secure for the hospitals the assistance they so badly needed.

Mr. RHYS DAVIES said he was not so sure that cases were not being sent to hospitals to-day which were ordinarily treated by the medical practitioner before the National Health Insurance scheme came into operation. Since the medical profession had a reduction of 1s. per annum in their panel fees that might be an additional argument for the proposition he was suggesting. He would leave it there, except to say that it seemed rather curious with regard to accident cases sent to hospitals that the Automobile Association could not take this question up in respect of their members. If a member of the Automobile Association came into conflict with the law the Association paid the legal changes and if they could do that from their annual contributions they ought to contribute something towards the medical and hospital charges of their members as well.

THE ELEMENT OF NOISE.

Mr. LOVAT-FRASER said the motor-car had introduced into our life an element that had greatly reduced comfort and pleasure—the element of noise. Was the Minister of Transport doing anything to mitigate that abomination? It was said that one got used to noise and that it did one no harm after a certain time. It did do one harm. (Cheers.) We all have a certain quantity of vital force and although we were not conscious of it that vital force was being used up in resisting noise. He asked the Minister to give them a word of assurance that something was being done to meet this growing evil.

HOUSE OF COMMONS.

THURSDAY, MAY 5TH.

Climatology and Health.

Mr. MCENTEE asked the Minister of Health whether, with a view to helping the Come-to-Britain movement, he would arrange for his medical officers to make a systematic study of climatology in relation to health, of the importance of providing facilities for cures, and of the way in which psychical influences may be developed.—Sir E. HILTON YOUNG replied: Attention is paid to the subject of climatology by the medical profession, and the subject is included in the course of study for diplomas in public health. The importance of facilities for treatment at health resorts is dealt with in a report on chronic arthritis issued by my department. I do not quite follow for what purpose the hon. Member recommends the development of psychical influences.

MONDAY, MAY 9TH.

Detention of a Feeble-minded Boy.

Dr. WILLIAMS asked the Minister of Health whether his attention had been called to the case of Harold Lee, who, owing to the effects of sleepy sickness, was paralysed and crippled, and who, instead of being sent to a suitable home, was detained at Rampton, an institution for mental defectives, where he suffered ill-treatment which necessitated the removal of his right eye; and whether he would cause an inquiry to be made into the conduct of this institution in order to ensure that, in future, only cases in which radical mental defect was present were kept there.—Mr. ERNEST BROWN replied: My right hon. friend's attention has been called to this case. Harold Lee is feeble-minded and partially paralysed. He was sent, in the first instance, to a residential special school for mental defectives, his mother having stated that he was dangerous and beyond her control. Owing to his violent behaviour he could not be retained at the special school, and was ultimately sent to the special block for children at Rampton. In May last year the patient, on his own admission, dislocated his own right eye, and this injury necessitated its removal. There is no foundation for the allegation that this was due to ill-treatment. The circumstances of the case have been very fully examined, and my right hon. friend does not consider that any further inquiry is called for.

Factory Accidents in India.

Mr. MORGAN JONES asked the Secretary for India if he could give information showing the total number of persons injured in accidents in those factories in India which were subject to the Indian Factories Act in 1931, or in the latest year for which figures were available; how many of these were cases of fatal, serious, and minor injury respectively; and what was the number of persons injured in this way per 100.000 of those employed in factories coming under the Act.—Sir S. HOARE replied: The figures for the year ending Dec. 31st, 1930, are as follows:—Number of fatal accidents, 240; serious, 4115; minor, 17.429; total, 21,784. Rate per 100.000: fatal, 15·7; serious, 269·2; minor, 1140·4; total, 1425.

Mr. MCENTEE asked the Secretary for India if he would give the latest available figures showing the number of factories in India coming under the Indian Factories Act, and the number of men and women factory inspectors employed under the Act.—Sir S. HOARE replied: The number of factories in India coming under the Indian Factories Act during the year 1930 (the latest year for which figures are available) was 8148. The number of factory inspectors employed under the Act during the year 1929 was 39, of whom one (in Bombay) was a woman.

TUESDAY, MAY 10TH.

Boy's Death on Spiked Railings.

Mr. MCGOVERN asked the Secretary for Scotland if his attention had been called to the fatal accident to the boy of 8 years of age at Parkhead, Glasgow, who fell on spiked railings; and if he would consider introducing legislation to give Scottish local authorities power to prevent the erection of such railings on buildings.—Sir ARCHIBALD

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

HEALTH AND SAFETY IN MINES.

In the House of Commons on May 3rd Mr. Isaac Foot, the Secretary for Mines, said the number of accidents in mines in 1931 gave some ground for encouragement as to the progress that was being made. The number of deaths in our coal-mines last year was the lowest in the history of the Department—namely, 859. That was 0·9 per 1000 of men employed, or 3·77 for every 1,000,000 tons raised. The serious accidents were 3304—the lowest on record. The smaller accidents—involving absence from work of more than three days—were about 140,000, or 26,000 less than in 1930 and 36,000 less than in 1929. Even allowing for the smaller number employed in the mines and although they were only taking the figures for one year, yet they regarded that as very gratifying. The real tragedy of the mines was the weekly return of accidents, not the big disasters. Everything that science could do must be done to make the big disasters impossible, but the real trouble of those concerned with health and safety was the daily cases. Taking the ten years from 1920 to 1929, for every casualty that arose from an explosion there were 1103 casualties arising from other causes. The most prolific cause of accidents was falls of ground. Next to that came haulage. One day they would have protective equipment in the mines. He had no doubt that in the future the use of helmets, gloves, safety boots, and goggles would be made compulsory. He was assured by those well qualified to speak upon it that a very substantial reduction in day to day accidents could be made by such simple precautions.

ACCIDENTS TO BOYS.

A most distressing feature of the returns was the number of accidents to boys. Last year 39 boys under 16 years of age were killed and 7000 boys under 16 were disabled by injury for more than three days. There was urgent need for more education. There had been printed pamphlets and circulars and the reports of the chief inspector and the eight divisional inspectors and the Department had carried through and completed the work started by his predecessor of holding safety conferences throughout the country. He would put on record his gratitude for the assistance given by the management and owners in helping to make those conferences a success. The expenditure of the Safety in Mines Research Board during the past year was about £50,000, which had been derived from the Miners' Welfare Fund. The importance of mine lighting was, first of all, because of the predominant medical opinion that the widespread disease of nystagmus was largely due to inadequate lighting and secondly because nothing contributed more to danger in the mines than the lack of proper lighting. Some months ago he had to consider whether a new regulation should not be issued establishing a new standard of lighting. He was anxious that they should not stereotype progress. He called together the representatives of the Mining Association and the Managers' Association and asked them to give him an assurance that during the next 12 months an improvement would be effected in this respect. That assurance was very readily given and the Department's inspectors were now at work throughout the country helping the recalcitrants and those who were behind their fellows in keeping up to the standard of these proposals. At the end of 12 months they would be able to consider whether the regulation ought to be imposed or whether their purpose had been achieved otherwise.

AN AMERICAN COMPARISON.

Sir Frederick Mills said that two or three years ago he went to America and visited a typical mine in Pennsylvania run by a company which was in part a subsidiary of the United States Steel Corporation. It was one of the nearly 30 mines which were producing something like 30,000,000 tons of coal per annum. The system of working there provided ventilation on twice the scale of anything in this country. There was also better light. In that area the accidents were considerably less than in this country. He suggested that the Secretary for Mines should send a small deputation of two or three mining members and agents to see this process in operation. They could get the price of coal very materially reduced by adopting this system which would be attended with much less risk to the workpeople and give them better working conditions.

BETTER ILLUMINATION.

Mr. T. Williams said that within the past few years there had been a great demand for improved lighting in the mines. A lamp called the Wolf safety lamp had been the leading lamp and the guiding influence in the deliberations of the Mines Department. This lamp gave the highest illumination of any miner's lamp in existence at the moment. Fortunately or otherwise some parts of the lamp were imported from Germany where the lamp had been tried out for many years and had given entire satisfaction. It was in no way in competition with any other lamp. Therefore to do anything that would retard the import of this lamp would be to deny the miner increased candle power and to increase the number of accidents. As a result of the exchange situation between this country and Germany, Britis importers of this lamp were suffering a tremendou disadvantage, and on top of that they had to fac an import duty of 10 or 20 per cent. which had well nigh put this particular firm out of existence s far as supplying lamps to this country was concerned He wished to know what the Mines Departmen had done to insist upon the Advisory Committe looking into this matter immediately and removing th duty. He had a report from an eminent expert on th question of nystagmus which gave proof beyon any shadow of doubt that as a result of the use of thi type of lamp miner's nystagmus had been reduce in many mines and would be reduced in the futur

THE SECRETARY'S REPLY.

Mr. Foot, replying to the debate, said that th question of the German safety lamp mentione by Mr. Williams must go before the Import Duti Advisory Committee. He had no power to interfer but the Department suggested that the importe might make representations to the Advisory Committe and if they communicated with the Department the would be happy to give them such information as w at their disposal.

NATIONAL HEALTH INSURANCE BILL.

On Thursday, May 5th, Sir E. Hilton Youn Minister of Health, presented the National Heal Insurance and Contributory Pensions Bill. Th measure amends the enactments relating to Nation Health Insurance, amends the Widows', Orphans and Old Age Contributory Pensions Act, 1925, b making provision for the payment of pensions ther under in respect of the insurance of persons wh cease to be insured within 12 months before deat or before attaining the age of 65, and modifies th statutory conditions applicable to such persons in th case of persons who, after ceasing to be insure again become insured.

The Bill was read a first time.

ROAD ACCIDENTS.

In the House of Commons on May 6th Mr. Pybu Minister of Transport, said he must touch on o point which was ever present in his mind and in th of the Home Secretary—namely, the appalli

Dr. E. Meinicke has been made an honorary professor in the University of Münster in recognition of his services to syphilology.

British Dental Hospital.

Sir Norman Bennett will preside at the annual meeting f this hospital to be held at the rooms of the British Dental Association, 23, Russell-square, W.C., at 8 P.M., on Thursday, May 19th.

Radium Institute, London.

Lord Dawson has been elected a member of the committee f this institute.

Research Defence Society.

Sir Arthur Keith, F.R.S., will deliver the Stephen Paget memorial lecture at the annual general meeting of this ociety, which is to be held at 3 P.M. on Wednesday, June 15th, in the lecture hall of the London School of Hygiene and Tropical Medicine, Keppel-street, W.C.

Malcolm Morris Lecture.

The fifth Malcolm Morris memorial lecture will be given under the auspices of the Chadwick Trust in the lecture hall of the Royal Society of Arts, John-street, Adelphi, London, at 5.15 P.M. on Monday, May 23rd. The lecturer will be Sir Ernest Graham-Little, and his subject Dermatology as an Outpost of Medicine.

Epsom College Royal Medical Foundation.

The Council of the College will shortly award a " France " pension of £30 a year to a duly qualified medical man of not less than 55 years of age. If the candidate is a single man or a widower, his income, independent of any allowance from the College or from the Royal Medical Benevolent Fund, must not exceed £100 per annum. If he be married, the combined income of himself and his wife must not exceed £150 per annum. Forms of application should be obtained forthwith from the Secretary, Epsom College, 49, Bedford-square, W.C.1, and must be returned, completed, to him not later than June 15th, 1932.

British Health Resorts Association.

At a conference held at Newquay last week-end it was resolved that a medical committee for the county of Cornwall should be formed to coöperate with the other committees in the south-western region of England and with the central organisation. Mr. J. C. Williams, Lord-Lieutenant of Cornwall, presided at the opening of the conference, and the speakers included Dr. F. G. Chandler, Dr. Fortescue Fox (chairman of the medical advisory committee of the Association), Dr. A. G. P. Hardwick (medical officer of health for Newquay), Sir Arthur Carkeek (chairman of the Cornwall County Council), Major Hilgrove McCormick (secretary of the Duchy of Cornwall), and Dr. W. Langdon Brown. Visits were paid to Falmouth, Penzance, Land's End, and St. Ives.

A regional conference of the Association will be held at Llandrindod Wells from May 20th to 23rd. The chairmen at the two sessions on Saturday, the 21st, will be Sir Humphry Rolleston and Sir William Willcox. On Sunday the conference will be entertained by the mayor and corporation of Aberystwyth.

Births, Marriages, and Deaths

BIRTHS.

Astley Cooper.—On May 2nd, at White Cross Nursing Home Edgbaston, Birmingham, the wife of T. Astley Cooper M.B., Ch.B., of a son.

Johnson.—On May 2nd, the wife of Athol J. Johnson, M.B., B.Ch. (W.A.M.S. reserve), of a son.

Parry.—On May 3rd, the wife of Wilson E. C. Parry, M.R.C.S., L.R.C.P., The Limes, Ampthill, Beds, of a son.

Shaw.—On May 7th, at Welbeck-street, the wife of Wilfred Shaw, M.D., F.R.C.S., of a son.

MARRIAGES.

McKinstry—Holman.—On May 7th, at All Souls' Church, Loudoun-road, N.W., William Kilbourn McKinstry, M.A. Camb., M.R.C.S. Eng., L.R.C.P. Lond., to Sibyl Mildred, second daughter of Dr. and Mrs. F. Kay Holman, of Avenue-road, Regent's Park, N.W.

Roche—Briggs.—On May 7th, at the Register Office, Kensington, Alex. E. Roche, M.D., M.Ch., F.R.C.S., to Cicely Mary, only daughter of Mr. and Mrs. Briggs, of 21, Wellington-road, Enfield.

DEATHS.

Gray.—On May 6th, at Dalreoch, Bournemouth, Alexander Gray, M.A., LL.B., M.D.

Legge.—On May 7th, at Wintergreen, Warlingham, Sir Thomas Morison Legge, M.D., C.B.E., Medical Adviser to the Trades Union Council, late of the Home Office, aged 69.

McClelland.—On April 13th, at Llwynwern, Dowlais, Glam, Robert Sloan McClelland, M.D.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, May 17th.—5 P.M., Special Meeting of Fellows: Nomination of Officers and Council. 5.30 P.M., General Meeting of Fellows: Ballot for election to the Fellowship.

Thursday.—5 P.M., Dermatology. (Cases at 4 P.M.) Annual General Meeting. Cases: Dr. H. W. Barber: 1. Unilateral Scleroderma Associated with Atrophy of the Subcutaneous and Muscular Tissues. 2. Sarcoid. Dr. H. D. Haldin-Davis: 3. Dermatitis Repens. Dr. Norman Burgess: 4. Pruritus Scroti Associated with Multiple Sebaceous Cysts. Dr. W. N. Goldsmith: 5. Epithelioma Adenoides Cysticum. 6. Cheilitis Exfoliativa. 7. Leiomyoma (photomicrographs). Other cases will be shown. 8 P.M., Neurology: Pathological Specimens. 8.45 P.M., Annual General Meeting.

Friday.—5.30 P.M., Physical Medicine. Annual General Meeting. 8.15 P.M., Obstetrics and Gynæcology: Annual General Meeting. 8.30 P.M., Radiology. Annual General Meeting. Slides illustrating cases of radiological interest will be shown by Dr. H. Courtney Gage, Dr. R. Fawcitt, and Dr. G. B. Bush.

ROYAL MICROSCOPICAL SOCIETY, B.M.A. House, Tavistock-square, W.C.

Wednesday, May 18th.—At 5 for 5.30 P.M., Prof. Hamilton Hartridge: 1. A Microscope Projector for Making Drawings. 2. A Microscope Projector for Lecture Purposes. Dr. P. R. Peacock, and Dr. L. Woodhouse Price: On the Cinematographic Examination of Serial Sections as an Aid to Histology.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (Manson House, 26, Portland-place, W.),

Thursday, May 19th.—8.15 P.M., Dr. F. W. O'Connor (New York): A Paper on the Ætiology of the Disease Syndrome in *Wuchereria bancrofti* Infections. Demonstration at 7.45 P.M. arranged by Dr. O'Connor.

CHELSEA CLINICAL SOCIETY.

Tuesday, May 17th.—8.30 P.M., preceded by a Dinner at 7.30 P.M. (at the Hotel Rembrandt, Thurloe-place, S.W.), Mr. Edward Mitchell will open a Discussion on Recent Developments in Domestic Architecture.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.

Thursday, May 19th.—2.30 P.M. (at 11, Chandos-street, Cavendish-square, W.), Quarterly Meeting. Dr. Edwin Goodall: The Exciting Cause of Certain States of Disease at present classified under " Schizophrenia " by Psychiatrists may be Infection.

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck-street, W.

Thursday, May 19th.—8 P.M., Annual General Meeting. Dr. J. C. Mottram: 1. On the Relationship of Beta and Gamma Radiation in the Treatment of Tumours; 2. The Action of Radium on Blood-supply—The White Reaction.

Friday.—11 A.M., Visit to the X ray department of St. Bartholomew's Hospital. 5 P.M., Cases. 5.30 P.M., Dr. S. Cochrane Shanks: X Ray Treatment of Ringworm. Dr. P. H. Whitaker: Hepatography and Lienography by Thorium.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.1.

Monday, May 16th to Saturday, May 21st.—London Light and Electrical Clinic, Ranelagh-road, S.W. An evening course in Physical Medicine. Mons. and Weds. from 8 to 9 P.M. Demonstrations on cases.—Maudsley Hospital, Denmark-hill, S.E. Afternoon course in Psychological Medicine.—St. John's Hospital, Leicester-square, W.C. Afternoon course on Dermatology. Clinical work at 2 P.M. and 6 P.M. daily, and lectures on Mond., Tues., Thurs., and Fri. at 5 P.M.—Clinical Pathology, 10, Bedford-square, W.C. Epidiascope and Laboratory demonstration by Dr. Knyvett Gordon on Wed. at 8.30 P.M., on Anæmia. (The above courses are open only to Members of the Fellowship of Medicine.)

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith-road, W.6.

Tuesday, May 17th.—10 A.M. to 1 P.M., Medical Wards, Surgical Demonstration, Throat Operations, Dental Department. 2 to 4 P.M., Operations, Medical, Surgical, and Throat Out-patients.

Wednesday.—10 A.M. to 1 P.M., Medical Wards, Children's Medical Out-patients. 2 to 4 P.M., Gynæcological Operations, Medical, Surgical, and Eye Out-patients. 4.45 P.M., Venereal Diseases Demonstration.

Thursday.—10 A.M. to 1 P.M., Neurological Out-patients Fracture Demonstration. 2 to 4 P.M., Operations, Medical, Surgical, Genito-Urinary, and Eye Out-patients. 4.15 P.M. (Lecture), Mr. Simmonds: Surgery of Joint Injuries.

Friday.—10 A.M. to 1 P.M., Medical Wards, Skin Out-patients, Dental Department. 12 noon, Medical Lecture. 2 to 4 P.M., Operations, Medical, Surgical, SINCLAIR replied: The answer to the first part of the question is in the affirmative. I am not satisfied, on the information before me, that legislation is required on this subject.

Mr. MCGOVERN asked if the right hon. gentleman was aware that since this question was put down another child had been impaled in Glasgow on spiked railings, and that numbers of workmen had slipped from roofs of buildings and had been killed in this way; and would the right hon. gentleman not consider doing something to save human life from this danger.

Sir A. SINCLAIR: I can only answer the question which has been put on the Order Paper. In that case the boy fell from a height of 30 feet, and if he had not fallen on the railings he would have fallen on the concrete pavement. If the local authority asks for powers their request will certainly be considered very carefully by the Government.

Accidents to Pedestrians.

Lieut.-Colonel MOORE asked the Secretary for Scotland whether his attention had been called to the report of the chief constable of Ayr, stating that nearly all accidents to pedestrians were caused by carelessness on the part of the injured persons; and whether he had received reports on this subject from other police authorities in Scotland.—Sir ARCHIBALD SINCLAIR replied: The answer to the first part of the question is in the affirmative. The statement of the chief constable was based on a detailed examination of the causes of accidents occurring in the county of Ayr during 1931. Some other chief constables have reported that in their districts a large percentage of accidents are due to carelessness on the part of pedestrians.

Lieut.-Colonel MOORE: Is the right hon. gentleman taking any steps in conjunction with the Minister of Transport to bring home to pedestrians their responsibility in this matter of street accidents?

Sir A. SINCLAIR: I will consider the suggestion of my hon. friend.

Experiments on Animals.

Mr. GROVES asked the Home Secretary the nature of the 12 experiments performed upon animals under Certificate A, without anæsthetics, during the year 1930 at the place No. 222 registered for vivisection; what premises constituted the aforesaid registered place; and what were the qualifications of the experimenters.—Sir HERBERT SAMUEL replied: The experiments referred to were the feeding of animals for the purpose of testing foodstuffs. The registered premises are the research laboratory of Messrs. J. and J. Colman's Carrow Works, Norwich; and the two experimenters were experienced research chemists.

Dental Treatment for the Police.

Mr. RICHARD RUSSELL asked the Home Secretary if he was aware that the provisions of his Order concerning dental treatment of the police were not being complied in the following areas: the county borough of Dewsbury, where a very low scale of fees formed the basis of the cost payable by the local police authority, the balance representing the difference, if any, between that scale and the fees of the private practitioner being payable by the officer; the city of Birmingham, where a scheme had been adopted in which no provision was made for the filling or scaling of teeth; and whether he was prepared to receive a deputation from the organisations representing the dental profession to discuss the difficulties which had arisen in connexion with the provision of dental treatment for the police.—Sir H. SAMUEL replied: I have made inquiry and cannot find that the arrangements made by the police authorities in question are in conflict with the police regulations. I will bear in mind the suggestion that I should receive a deputation, but I do not think that there is occasion for it at present.

MEDICAL NEWS

University of London.

Among appointments to the Senate for 1932–36, Lord Dawson has been reappointed by the Faculty of Medicine, and Dr. A. M. H. Gray by the General Medical Schools.

University of Edinburgh.

On May 5th the following diplomas were conferred:—

Diploma in Public Health.—*Euphemia T. Guild and *Janet C. Ronaldson.

Diploma in Psychiatry.—C. D. Bruce, *A. S. M'Culloch, and Flora M. Stewart.

Diploma in Tropical Medicine and Hygiene.—*J. E. Dovey, *J. M'K. A. Lowson, and Thomas Menzies.

* = In absentia.

Royal College of Physicians of Edinburgh.

At a quarterly meeting of the College on May 3rd, with Dr. Robert Thin, the President, in the chair, Dr. William Lindsay Lamb (Aberdeen) took his seat as a Fellow, and Dr. John McIntosh Morgan (Dundee) was elected to the Fellowship. Sir Norman Walker was elected a representative of the College on the committee of management of the Triple Qualification. Dr. A. Fergus Hewat was elected a trustee of the College. Dr. Edith Kate Dawson was awarded the Lister Fellowship for original research.

Marie Curie Hospital.

The annual meeting of this hospital was held on May 6th, Miss Chadburn, M.D., the chairman of the board of management, presiding. Sir Cuthbert Wallace spoke on radium therapy and on the good work being done at the hospital, and Mr. G. K. Chesterton then proposed the re-election of the board of management. The report showed that since the Marie Curie Hospital Clinic was begun in 1925, over 700 cases of uterine cancer have been treated with radium, and during 1931, 145 of these cases were treated; also 29 cases of cancer of the breast, 6 of cancer of the rectum, and 152 cases of non-malignant uterine hæmorrhage. Nearly 80 per cent. of the uterine cases applying at the clinic are advanced when first seen. Special appreciation was expressed by Dr. G. Hurdon, the director of research, of the work of the Follow-up Committee organised by Lady Fletcher; a very large proportion of the patients treated during the whole life of the hospital have been traced, and are periodically visited if they do not report progress. The charges for beds in the private wards are from 5 to 15 guineas per week, according to accommodation; and patients in the general wards contribute up to 3 guineas weekly according to their means.

Institute of Medical Psychology.

The annual meeting and luncheon of this Institute (formerly the Tavistock-square Clinic) will be held at the Hotel Great Central, Marylebone-road, London, N.W., from 12.15 to 2.45 P.M. on Tuesday, May 31st.

National Association for the Deaf.

The Lord Mayor of London, Sir Maurice Jenks, will preside at the eighth annual meeting of this association, which will be held at the Mansion House at 3 P.M. on Friday, May 27th. The speakers will include the Archbishop of Canterbury and Lord Charnwood.

London Hospital Medical College.

A course of six lectures on the Structure of Molecules in Relation to Biology and Medicine will be given by Dr. J. R. Marrack in the Bearsted clinical theatre of the London Hospital at 5.15 P.M. on Tuesdays and Thursdays from June 14th to 30th. The course is open to students of London University and to members of the medical profession.

Fellowship of Medicine and Post-Graduate Medical Association.

Four similar "refresher" courses in medicine, surgery, and the special departments will be given at the Prince of Wales's General Hospital, Tottenham, from May 23rd to June 4th, June 6th to 18th, June 20th to July 2nd, and July 4th to 16th. There will be lectures and demonstrations daily from 10.30 A.M. to 5.30 P.M., with instruction in the out-patient departments. Antenatal demonstrations will be given at the Royal Free Hospital by Dame Louise McIlroy at 5 P.M. on Wednesdays, June 1st to 22nd. An all-day course in gynæcology will be held at the Chelsea Hospital for Women from June 6th to 18th, and one in diseases of the chest at the City of London Hospital, Victoria Park, from June 6th to 18th; there will also be a week-end course on diseases of the chest at the Brompton Hospital, on June 25th–26th. A series of three epidiascope and laboratory demonstrations will be given by Dr. Knyvett Gordon at 10, Bedford-square, at 8.30 P.M., on Wednesdays, May 18th and 25th, and June 1st. The subjects will be Anæmia, Hæmorrhage, and Splenic Enlargement. Three lectures on Epidemic Encephalitis will be given by Prof. Arthur Hall, at 8.30 P.M., on Thursdays, June 2nd, 9th, and 16th. The first and last lectures will be delivered at 11, Chandos-street, W., and the second (with a cinema demonstration) at Bush House, Aldwych. All courses and lectures are open only to members of the Fellowship of Medicine, whose office is at 1, Wimpole-street, W.1.

NOTES, COMMENTS, AND ABSTRACTS

THE HEALTH OF HENRY VIII.

Mr. Frederick Chamberlin, who has already written about the Private Character of Queen Elizabeth, now publishes a similar volume about her father King Henry VIII.[1] He has collected his facts from many sources, chiefly the State papers in England, France, Spain, and Italy, and has produced a graphic picture of Henry as a man. The chief interest for medical readers is the attempt to answer the often repeated accusation that the King had acquired syphilis and that his comparative failure of issue with the consequent matrimonial troubles was due to this cause. The conclusion at which Mr. Chamberlin arrives after a consideration of the facts now attainable are that at the best a verdict of Acquittal and at the worst one of Not Proven must be given. Born in 1491, six years after the battle of Bosworth Field, Henry was the second son and third child of Henry Tudor and Elizabeth of York, his father being 34 and his mother 26. Like his contemporary Gargantua he came into the world with the physique of a giant, broad and lusty, a mighty trencherman, assertive, proud, bubbling over with high spirits, and yet as Erasmus says of him at the age of 8, with something of Royalty in his demeanour and having a certain dignity combined with a singular courtesy. A musician by heredity, he was a regular chorister at the Chapel Royal at 10, and before he was 12 had written many pieces of Church music. Throughout his life he was an accomplished player on every kind of musical instrument from the organ to the flute. From early youth until the age of 44 he was a keen and constant dancer. The Spanish Ambassador, writing of him at the age of 16, says, "there is no finer youth in the world. He is already taller than his father and his limbs are of gigantic size." He was 6 ft. 2 in. in height when he was 23, measuring 42 in. round the chest and 35 in. round the waist. During the whole of his active life he was a mighty hunter, shooting deer with the crossbow, and a champion jouster when jousting was the national sport of the nobility of England and France. He fought in plate armour both on foot and mounted, and by sheer physical force could overthrow his adversary similarly accoutred. He was nearly killed at the age of 34 whilst tilting with the Duke of Suffolk. Riding with his visor up in a new helmet of his own invention the Duke's lance was shivered against the King's forehead and from this time onwards he began to complain of headaches. Ten years later, on Jan. 24th, 1536, the King being mounted on a great horse at Greenwich to run at the lists, both man and horse fell so heavily that all thought he was dead. It was reported to the French King that he lay without speaking for two hours and had not improved in consequence of the fall.

The state of Henry's health was a matter of vital importance in international politics, and the accredited agents made careful reports to their respective governments whenever he was ill. There was, however, very little to say, for he was singularly healthy until he reached middle age. A few colds in the head, one with hoarseness; measles or small-pox in 1514; a slight fit of ague in 1539 and toothache from time to time is all that could be stated about him, except that a trouble in connexion with his leg is mentioned on March 24th, 1537, when he was 45 years of age. The physicians at some unknown date previously had ordered an issue to be made. The issue never healed and eventually became an ulcer, which was occasionally painful, and on two occasions, once in 1538 and again in 1541, gave rise to symptoms possibly associated with an embolus. It was probably of the nature of a varicose ulcer, says Sir D'Arcy Power, to whom the question was referred as a point of some historical significance. This appears a likely explanation, for Sir Geoffrey Pole reported in November, 1538, that the King "had a sore leg that no poor man would be glad of." Throughout the medical record there is no mention of a mercurial course, a method of treatment which was well understood and was always advised by the surgeons of the period if there was the least suspicion of syphilis. The course took many weeks from beginning to end and could not have remained unknown to the Court. It is certain therefore that the King's physicians did not consider the ulcers to be syphilitic.

The obstetric history also bears out the non-syphilitic character of the abortions which occurred in the consorts of the King. Dr. J. W. Williams, professor of obstetrics at the Johns Hopkins University, believes that "no one has yet adduced evidence that syphilis is an important factor in the production of abortion in the first few months of pregnancy, and there is nothing in the history of Mary or Elizabeth to indicate that they had congenital syphilis." Dr. Eardley Holland reports that "there is nothing in the reproductive history of Elizabeth Blount, of Anne Boleyn, or of Jane Seymour even to suggest syphilis, and we are therefore left with the consideration of Catherine and the repeated stillbirths. Those who have investigated the causation of stillbirths are generally agreed that only about one in three cases of repeated stillbirths are due to syphilis; and in the syphilitic cases there usually occur also the births of living children with signs of the diseases either at birth or later in life. So far as I can gather there is no evidence that Queen Mary suffered at any time from congenital syphilis, nor does there appear to be any evidence that the child born in January, 1511, who lived for 52 days only, ever showed any signs of the disease." Prof. F. Williams, of the University of Pennsylvania, expresses himself more cautiously when he says "the medical history of the lives of Mary, Elizabeth, Edward and Richmond do not throw any direct light upon the question of their father being syphilitic unless one judges congenital defects and constitutional inferiority to be evidence of an inherited syphilis." No one could accuse Elizabeth of being constitutionally inferior; Mary suffered for many years from an ovarian tumour; Edward VI., like his uncle, Prince Arthur and his brother the Duke of Richmond, died of tuberculosis. It can therefore be safely assumed in the light of Mr. Chamberlin's researches that Henry VIII. did not suffer from syphilis.

CORRIGENDUM.—Dr. S. C. Dyke writes regretting that in his article on the treatment of diabetes with higher carbohydrate diets, appearing in THE LANCET of last week, he confused Dr. F. M. Allen, of New York, the founder of the modern treatment of diabetes, with Dr. F. N. Allan, of the metabolic department of the Mayo Clinic.

and Throat Out-patients. 4.15 P.M. (Lecture), Mr. Batchelor: Diseases of the Rectum.
SATURDAY.—9 A.M. to 1 P.M., Throat Operations, Medical and Surgical Wards, Surgical and Children's Medical [illegible] ctures at 4.15 P.M. on Mondays, and Fridays are open to all without fee.

NATIONAL HOSPITAL, Queen-square, London, W.C.
TUESDAY, May 17th.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Mr. Julian Taylor: Spinal Injuries.
WEDNESDAY.—2 P.M., Dr. Martin: Out-patient Clinic.
THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Riddoch: Neurosyphilis.
FRIDAY.—2 P.M., Dr. Adie: Out-patient Clinic. Mr. Elmquist: Demonstration of Re-educative Exercises.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.
MONDAY, May 16th.—4 P.M., Mr. V. Z. Cope: Demonstration of Surgical Cases.

LONDON JEWISH HOSPITAL, Stepney Green, E.
THURSDAY, May 19th.—4.15 P.M., Mr. J. Lauer: Dental Treatment in General Medicine.

HOSPITAL FOR EPILEPSY AND PARALYSIS, Maida Vale, W.
THURSDAY, May 26th.—3 P.M., Dr. Douglas McAlpine will demonstrate.

UNIVERSITY COLLEGE, Gower-street, W.C.
THURSDAY, May 19th.—5.30 P.M., Dr. C. S. Myers: Absurdity of any Mind-Body Relation (Hobhouse Memorial lecture).

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.
THURSDAY, May 19th.—5 P.M., Dr. I. Muende: Pathological Demonstration.
FRIDAY.—5 P.M., Dr. W. Griffith: Bullous Eruptions.

ST. PAUL'S HOSPITAL, Endell-street, W.C.
WEDNESDAY, May 18th.—Mr. S. Cade: Radium in Treatment of Cancer of Prostate.

ST. MARK'S HOSPITAL, City-road, E.C.
THURSDAY, May 19th.—4.30 P.M., Mr. W. B. Gabriel: Elucidation of Rectal Symptoms (Irritation).

ST. PETER'S HOSPITAL, Henrietta-street, Covent Garden, W.C.
WEDNESDAY, May 18th.—3 P.M., Dr. E. J. Roth: Radiological Investigation of the Kidney.

NATIONAL CENTRE AND POST-GRADUATE SCHOOL OF RADIOTHERAPY, Riding House-street, W.
WEDNESDAY, May 18th.—4.30 P.M., Mr. M. Donaldson: Radiotherapy and Gynæcology.

ROYAL INFIRMARY, Glasgow.
WEDNESDAY, May 18th.—4.15 P.M., Dr. A. M. Crawford: Medical Cases.

Appointments

ERSKINE, W. A., M.B., Ch.B. Edin., has been appointed Medical Officer to the Post Office at Bristol (District 6).

RUSHWORTH, J. A., M.R.C.S., L.R.C.P. Lond., Assistant Tuberculosis Officer in the Liverpool Health Department.

STEWART, D., Certifying Surgeon under the Factory and Workshop Acts for Newtyle District, Angus.

London County Council: **McMAHON, T. B.**, M.D. Dubl., Assistant Medical Officer (Grade II.), St. Pancras. **WALLACE, W. H. S.**, M.B., B.S. Lond., D.P.H., Assistant Medical Officer (Grade II.), St. Luke's, Chelsea; **HEATHCOTE, Columba**, M.B., B.Ch., B.A.O. Dub., Assistant Medical Officer, (Grade II.), St. Benedict's; **MASON, J. H.**, M.B., B.S. Lond., Assistant Medical Officer (Grade II.), Archway; Hunter, A. I., M.B., Ch.B. New Zealand, Assistant Medical Officer (Grade II.), St. Mary (Islington); Hill, R. A., M.B., B.S. Lond., Assistant Medical Officer (Grade II.), Highgate.

Vacancies

For further information refer to the advertisement columns.

Altrincham General Hospital.—Sen. and Jun. H.S. At rate of £150 and £120 respectively.
Banbury, Oxon, Horton General Hospital.—Res. M.O. At rate of £150.
Barrow-in-Furness, North Lonsdale Hospital.—H.S. £175.
Bedford County Hospital.—Second H.S. At rate of £140.
Birmingham and Midland Eye Hospital, Church-street.—Two Out-patient Officers. Each 1 guinea per session.
Birmingham, Queen's Hospital.—Surgeon for Out-patients. £50.
Brighton, Royal Sussex County Hospital.—Cas. H.S. £120.
Bristol, City and County of.—Asst. M.O.H. £500.
Bristol General Hospital.—Hon. Obstet. Phys. and Gynæcologist, Hon. Asst. Obstet. Phys. and Gynæcologist, also Hon. Surg. and Hon. Asst. Surg.
Bristol, Queen Victoria Jubilee Convalescent Home.—Surgeon. £120.
Buxton, Derbyshire, Devonshire Hospital.—Asst. H.P. At rate of £150.
Camberwell House, London, S.E.—Third Asst. M.O. £300.
Cardiff, City Lodge Institution.—Asst. M.O. £150.
Cardiff, Welsh National School of Medicine.—Chair of Obstetrics and Gynæcology. £300.
Carlisle [illegible]
Chester, [illegible] 00.
Chester [illegible]
Chester [illegible] £150.
City of [illegible] Res. M.O. At rate of £80 to £100.
Colchester, Essex County Hospital.—Asst. H.S. £120.
Coventry and Warwickshire Hospital.—Res. Cas. O. £125.
Cumberland, Blencathra Sanatorium, Threlkeld.—Asst. Med. Supt. £300.
[illegible] *ry.*—Ophth. H.S. £150.
[illegible] H.S. At rate of £175.
[illegible] Welfare M.O. £500.
[illegible] £450.
East Ham County Borough.— [illegible]
Edmonton, Edmonton and [illegible] *street.*— Consultant Neurologist. [illegible]
Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—H.P., Obstetric Asst. Also three H.S.'s. Each at rate of £50.
Evelina Hospital for Sick Children, Southwark, S.E.—H.P. At rate of £120.
Glasgow Royal Mental Hospital.—Physician Supt.
Glasgow University.—Tennent Chair of Ophthalmology.
Glasgow, West of Scotland Neuro-Psychiatric Research Institute.—Director. £850.
Gloucester, Gloucestershire Roy [illegible] Surgeon.
Hospital for Sick Children, [illegible] *.C.*—Part-time Jun. Cas. O. At r[illegible] and H.S. Each at rate of £100.
Hounslow, Heston and Isleworth U.D.—Asst. M.O.H. and Schoo[illegible] M.O. £500.
Ilford, King G [illegible] At rate of £100.
Ipswich, East [illegible]
Kidderminster [illegible]
Kingston-upon- [illegible] *Hospital.*— [illegible] rate of £100.
Lincoln County Hospital.—Jun. H.S. At rate of £150.
Liphook, Hants, King George's Sanatorium for Sailors.—Asst. M.O. At rate of £200.
Liverpool, Smithdown-road, Hospital.—Res. Asst. M.O.'s. Each £200.
L.C.C. District 11, Area IX., Deptford.—Temp. District M.O. £210.
London Light and Electrical Clinic, Ranelagh-road, S.W.—Hon. Consultant Gynæcologist.
London University.—Graham Scholarship in Pathology.
Maidstone, Kent County Ophthalmic and Aural Hospital.—Ophth. H.S. At rate of £200.
Manchester.—Asst. M.O. for Crossley Sanatorium, Delamere Forest, Cheshire. £200.
Manchester, Ancoats Hospital.—H.P. At rate of £100.
Manchester Babies Hospital, Burnage-lane, Levenshulme.—Jun. Res. M.O. At rate of £50.
[illegible] *-road, E.*—Cas. O. £100. Also [illegible] hroat Department.
[illegible] st. M.O. for Harmondsworth [illegible] Vaccinator.
[illegible] H.S. £175.
[illegible] *tal.*—Res. H.S. £150.
[illegible] *st India Dock-road, E.*—Second [illegible] O. £150.
[illegible] *pital, Marylebone-road, N.W.*— [illegible] Dist. Res. M.O. At rate of £80.
Queen Mary's Hospital for the East End, E.—Res. M.O. At rate of £200. Also Cas. O., H.P.'s and H.S.'s. At rate of £150, and £120 respectively.
Reading, Royal Berkshire Hospital.—H.S. £150.
Royal Free Hospital, Gray's Inn-road, W.C.—Cas. O. At rate of £150.
Samaritan Free Hospital for Women, Marylebone-road.—Hon. Surg. to Out-patients.
South London Hospital for Women, Clapham Common, S.W.—M.O. in charge of Venereal Diseases Clinic.
South Shields, Harton Hospital.—Two H.S.'s. £150.
Surrey C.C.—Asst. M.O. £600.
Truro Royal Cornwall Infirmary.—H.S. £170.
Ventnor, I. of W. Royal National Hospital for Consumption.—Sen. Asst. Res. M.O. £100.
Wakefield, West Riding of Yorkshire C.C.—Asst. Tuber. O £500.
Warrington Infirmary and Dispensary.—Jun. H.S. £175.
West End Hospital for Nervous Diseases, Welbeck-street, W.—Hon. Anæsthetist.
Wrexham and East Denbighshire War Memorial Hospital.—Hon. Ophthalmic Surgeon.

The Home Secretary gives notice of a vacancy for a Medica Referee under the Workmen's Compensation Act for th Atherstone and the Lichfield, Stafford, Tamworth, an Uttoxeter County Court Districts. Applications for th post should reach the Private Secretary, Home Offic Whitehall, London, not later than May 28th.

POPLAR HOSPITAL FOR ACCIDENTS.—The trustee of the Bernhard Baron estate have given £10,00 to this hospital to be spread over a period of fiv years. It is to be allocated to the fund for rebuilding th out-patients' department. This work is likely to cos £30,000, and at least another £10,000 will still be neede to complete it.

ADDRESSES AND ORIGINAL ARTICLES

HE CONTROL OF CARBOHYDRATE METABOLISM.[*]

J. J. R. MACLEOD, M.B. ABERD., D.SC., LL.D., F.R.C.P. LOND., F.R.S.,
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF ABERDEEN.

HAVE chosen as the subject of this year's Linacre ure one in the study of which there has always ı the closest collaboration between physician and erimentalist. Perhaps more than in any other ase have the problems arising in the clinical estigation of diabetes been helped towards solu- by the discoveries of the laboratory. and the arches through which these have been made e, in many instances, been inspired and cted by what the physician has observed at the side.

o the physiologist the problem of the control of metabolism of the carbohydrates has a further erest. since it seems to him that its solution must the first step towards revealing the mechanism of tabolism in general. This mechanism is no doubt tly dependent upon the balance established at h stage among the various substances which are ng constantly built up and broken down, in a state dynamic equilibrium. But. whilst this is intelli- le when we restrict our consideration to processes urring in simple solution within a single cell, ere remains to be explained how coördination is ected between these processes in different cells in dely separated organs. or even in different regions the same cell. It is conceivable that in metabolism e rate of reaction at any of the intermediary stages capable of being altered by something affecting ther the activity of the enzyme that controls it the solution pressure of the reacting substances. ne or other of these may be influenced either through e nervous system or by hormones. The nervous stem may alter the rate of change through its ntrol over the intimacy of contact between enzyme nd substrate, as by increasing or decreasing the ermeability of the intracellular barriers which old the two apart, and hormones may influence either for the same reason or because of an ctivating or inhibiting influence on the enzyme self.

Since most metabolic processes, especially those f protein and fat, appear to proceed at a steady ate, as evidenced by the constancy of the excretory products under basal conditions, it is unlikely that nervous control can play any significant rôle in their regulation. But there are certain processes of carbohydrate metabolism in which this method of control may be important. the most outstanding being the chemical changes which accompany muscular activity. When the glycogen of the muscles becomes used up in the production of lactic acid, the supply is replenished by glucose derived through the blood from the liver. Our first question in the control of carbohydrate metabolism is, therefore, how is this correlation between muscles and liver effected ? When the muscles contract, do they set up through their sensory nerve-endings impulses which, acting by way of some nerve centre, stir up the liver to produce more sugar ? Or is the process purely a chemical one in the sense that when the sugar of the blood becomes used up to meet the increased demands of the muscles for material out of which to replace their glycogen, the resulting hypoglycæmia stimulates sugar production in the liver, either by a direct action on its cells, or indirectly by influencing the secretion of some hormone which then has this effect ? However mediated, the control between the requirements of the muscles for glucose and its production by the liver must be a finely balanced one, as is well illustrated both by the constancy of the blood-sugar level during moderate exercise and by the small extent to which the percentage of glycogen in the muscles may be decreased even after the exercise has been long continued (Hershey and Orr[1]).

The aim of the physiologist is essentially to resolve general questions such as these into specific problems capable of being investigated by experimental methods. If, as Pflüger[2] first suggested, the correlation between muscular activity and carbohydrate metabolism is of the nature of a nerve reflex, causing alterations in the rate of sugar production in the liver, then it should be possible to demonstrate the efferent nerve control of this process, and the actual problem first to be considered concerns the method to be used for ascertaining the rate of sugar production.

Significance of Changes in Blood-sugar Level.

The conditions met with in the phenomena involved in the regulation of the blood-sugar level are far more complex than those we have to deal with when studying the activity of some gland which discharges its secretion through a duct. since the sugar is added to the large volume of blood which circulates through the liver. Alteration in the rate of production of sugar can be detected only when it is sufficiently great to cause a measurable change in concentration, and even then it is not permissible to infer that this is the factor involved unless the possibility of a change in concentration through migration of sugar from the blood into the tissues has been ruled out. The percentage of sugar in the blood. in other words, is merely a balance between production and loss. If the rate of either of these is known to be constant, changes in the sugar concentration must reflect alterations in the speed of the remaining process. When muscular activity is at its lowest and is uniform, as indicated by constancy in the consumption of oxygen—the basal state—a change in the blood-sugar level would suggest an alteration in the rate of sugar production by the liver and. conversely, when the latter is constant, as is presumably the case after the absorption of food from the alimentary canal is completed—the post-absorptive state—changes in the level must be the reflection of variations in the rate of utilisation of sugar by the tissues. That this behaviour of the blood-sugar level is the most important index we have of the state of carbohydrate metabolism has been amply confirmed through practical experience. When in the basal state the level is found to be higher than its average, one or other of the processes of carbohydrate metabolism is certainly disturbed, and the onset of this disturbance may be revealed by observing the extent to which the level becomes raised by adding sugar to the blood directly, or by the alimentary tract.

MENTAL DISEASES IN THE NEAR EAST.

THE pioneer work of Dr. John Warnock among mental sufferers in Egypt is paralleled by that of the less well-known Lebanon Hospital for Mental Diseases in Syria, Palestine, and the surrounding countries during the last 32 years.

The report of Prof. Watson Smith, who has been medical director for 23 years, was presented at the annual meeting of subscribers held in London on May 4th. From a small beginning, this voluntary hospital has become one of the most important branches of the public assistance and medico-legal services of Syria, and its benefits to the individual are indicated by the fact that 3714 patients have now been under treatment there. A new house, with 40 beds, has been added during the year, bringing up the number of houses to 11, and of beds to 240. The patients show great variety of race and religion, and range from the rich and influential to the destitute and nameless. During the year 154 were admitted (112 men and 42 women), making 373 under treatment (237 men, 136 women), of whom 18 died, and 36 were discharged recovered, 49 relieved, and 8 not insane. At the annual meeting Dr. Doris Odlum pointed out that the proportion of recoveries was good compared with English work, also that the average duration of residence was only about one month—a much shorter time than in English mental hospitals, even in those for early nervous breakdown. Its importance as a training centre for mental nurses, on whose skill the progress of these patients so much depended, and for medical students who would later go out as doctors all over the Near East, could not be over-estimated. Dr. Watson Smith's work as lecturer in psychiatry at the University of Beirut was a most important supplement to his clinical work and teaching in the village six miles away. The hospital had passed safely through the period of the Great War, and with the help of the charitable public would surmount the Great Depression.

Dr. E. W. G. Masterman, chairman of the London committee, who presided, presented the general report, and pointed to the steady progress made year by year, and the importance of its international character in composition and in support. Drs. Percy Smith and Fortescue Fox, members of the committee since its beginning, spoke in whole-hearted support. Mr. Hourani, a Syrian member of the committee, bore witness, from personal knowledge, of the horrors from which this one and only mental hospital had saved many of his compatriots. Pastor Christol, a French missionary, told from experience of what it meant to live in Central Africa, where there was no attempt to deal with the insane; capping Dr. Odlum's account of Morocco, where these unhappy people were chained by the neck in semi-darkness in stone chambers in the heart of a city, by describing the more primitive method of abandonment in the forests. He pleaded that, later London committee, with the aid of its ... countries, should do something ...ially for its suffering insane ... ear Beirut, and the ... DIPHTHERIA IMMUNISATION: A MISSTATEMENT.

A LETTER has appeared in Kentish newspapers, over the signature of H. W. McCleery, describing the last three sentences of an annotation entitled Diphtheric Immunisation in THE LANCET of Jan. 30th (p. 252) as "an admission of the utmost significance and importance." It is clear, we wrote, that toxin-antitoxin mixtures should be given up. "This toxin-antitoxin is," the letter states, "the immunising serum in general use." As far as this country is concerned the statement is untrue. For many years past the diphtheria prophylactic used for immunisation in Great Britain has been almost exclusively prepared from toxin detoxicated by formalin (toxoid) either in combination with antitoxin or alone. After the Bundaberg accident in 1928, the already strict regulations under the Therapeutic Substances Act were made still more strict regarding the preparation and testing of this type of prophylactic. For at least two years past it is probable that no toxin-antitoxin mixtures, properly so-called, have been sold in England. Immunisation has been carried out with toxoid-antitoxin mixtures or toxoid alone. It was clearly stated in the annotation that all possible source of danger can be avoided by using, instead of toxin, the modification of toxin prepared by heating it with formalin.

THE DESOUTTER CUSHION-JOINT FOOT.

Mr. Charles Desoutter, who devised the light metal limb of which some 5000 are being delivered each year, has now put on the market a foot joint which is a definite improvement on anything hitherto supplied. Wearers of existing models find it necessary from time to time to adjust and oil the joint mechanism and to fit new rubbers in position. By the introduction between the foot piece and the leg piece of a cushion unit which requires no such attention, the normal action of the gastrocnemius muscle in walking has been closely imitated and more elasticity given to the gait. The construction is simple, the so-called cushion-joint unit being fixed to the foot by a single nut, the tightening of which does not affect the working of the joint; the nut itself is locked by a serrated washer, and the whole is sealed by a sunk disc. The action can be regulated to suit every type of amputation. The flat foot is attached to a shin piece, drawn out of a flat sheet of duralumin to avoid any danger of seam corrosion and breakage, which combines strength and lightness. The wearer of the artificial limb will certainly do well, if he can afford it, to try this new type of joint. The chief fitting centre of the Desoutter Service is at 73, Baker-street, London, W.1, with branches at ten provincial centres, as well as in Wales, Scotland, and Ireland.

MATERNITY AND CHILD WELFARE.—The National Conference on Maternity and *Child Welfare* will be held at the Guildhall, King-street, London, E.C., from July 4th to 6th. Children and to the East ... d ... provisional programme of ... d ... the conference may be had from the hon. secretary at 17, Piccadilly, W.1.

t hyperglycæmia occurred only when the pons s involved. Thus in 23 experiments on fasted bbits the average blood-sugar rose to nearly 00 per cent. within four hours after decerebrating ough the pons. On the other hand, when decereation was at other levels the blood-sugar either mained unaltered or only rose slightly. These ults are shown in Table I., in which position I. cludes those regions of the brain anterior to the uber cinereum; position II. between the tuber and e upper border of the pons; position III. the pons; nd position IV. the medulla.

BLE I.—*Average Behaviour of Blood-sugar Percentage after Decerebration (decn.) at Various Levels.*

si-on f cn.	Blood-sugar percentage.						Expts.
	Before.	Immediately after.	In 1 hr.	2 hrs.	3 hrs.	4 hrs.	
I.	0·102	0·127	0·139	0·145	0·155	0·174	10
II.	0·123	0·125	0·125	0·139	0·130	0·160	6
II.	0·110	0·155	0·195	0·241	0·286	0·291	23
V.	0·109	0·137	0·123	0·135	0·131	0·126	10

The method of approach to the pons varied in ifferent experiments, being sometimes through a ephine hole in the skull and sometimes through the ccipito-atlantoid space, and from post-mortem xamination of the brains we are inclined to believe hat "the centre" is situated in the tegmentum of he pons. It is possible, as has been stated to be he case by Hiller,[11] that it is the vestibular nuclei r those having to do with muscle tone that are specially concerned. The view that the motor ucleus of the tenth nerve is the centre, as asserted y Brugsch, Diesel, and Lewy,[12] is in no way suported by our results. My colleague, Peterson, has ecently confirmed them. He has found in cats nder anæsthesia by ethyl chloride or nitrous oxide hat the blood-sugar level is only moderately raised fter decerebration in region II. In an hour or so it sually returns to the normal level but rises immeiately and continues to rise if a second decerebration s performed in region III.

The question, whether the transection owes its iabetogenic effect to stimulation of a centre or to everance of some nerve pathway, is a difficult one o answer. The former view receives some support rom the fact that a striking degree of hyperglycæmia ften follows when the transection is considerably o one or other side, or is of limited width in the midine, a mere puncture being sometimes effective, at east in the rabbit. If severance of some pathway hould prove to be responsible for the hyperglycæmia we will be compelled to conclude that impulses having a general hypoglycæmic effect (perhaps because they maintain a secretion of insulin) are constantly escending from some centre above the level of the ransection. Such a centre would have to be within the pons or the adjacent regions of the cerebellum, since, as we have seen, transection immediately anterior to this region leaves the blood-sugar level unchanged. But inasmuch as section of the medulla in the rabbit is also without hyperglycæmic effect, it seems likely that mechanical stimulation rather than destruction of some centre in the pons is esponsible for the hyperglycæmia.

Nature of Metabolic Disturbance Responsible for the Hyperglycæmia.

Provided with an experimental method by which hyperglycæmia could with certainty be induced, the question arose as to the nature of the metabolic disturbance responsible for it. In his earlier experiments on piqûre, performed before he discovered the presence of glycogen in the liver, Claude Bernard considered that the hyperglycæmia was due to excessive secretion by the liver of sugar derived from protein and fat. But this view was later replaced by one in which it was considered that the extra sugar arose from the glycogen existing in the liver at the time of performing the piqûre. The reasons for this change of view were that the glycosuria which developed when piqûre was performed on rabbits having small stores of hepatic glycogen, as a result of fasting, was less marked and of shorter duration than in well-fed ones, and that its disappearance in the latter seemed to coincide with depletion of the glycogen stores. It is probable, however, that subsidence of the irritation caused by the piqûre —perhaps through death of the nerve structures— was responsible for the disappearance of the glycosuria.

On repeating these experiments on fasting or well-fed rabbits, Donhoffer and I have found that the hyperglycæmia which follows pontine transection is as pronounced in animals having only traces of glycogen in the liver to start with as in those with large amounts. Thus, when we compare the average percentages of sugar in blood removed at hourly intervals after decerebration in a group of animals having less than 2 per cent. of liver glycogen with those in a group having over 2 per cent. the following are the results,

TABLE II.—*Average Blood-sugar Percentages at Hourly Intervals. Before and after Decerebration.*

Liver glycogen.	Normal.	Immediate.	1 hr.	2 hrs.	3 hrs.	4 hrs.	Expts.	Glycogen.
Below 2 p.c.	0·107	0·155	0·195	0·243	0·284	0·277	8	Under 1 p.c. in 4 cases.
Over 2 p.c.	0·109	0·149	0·165*	0·218	0·280*	0·287	6	Over 5 p.c. in 5 cases.

* Only 5 in average.

The hyperglycæmia is seen to have been practically of the same degree in the two groups, but the change in the glycogen percentage was very different, as will be seen by referring to Table IV.; a small reduction occurring in the fasted animals but a large one in those that were well fed. It is quite evident, in the fasted animals at least, that sugar production out of glycogen in the liver cannot account for the extra sugar in the blood, and indeed, in several of these animals, the glycogen percentage in this organ actually became increased following decerebration.

These observations show that the effects of decerebration cannot depend merely on increased production of sugar from the glycogen originally present in the liver.

What then causes the blood-sugar level to rise after decerebration? Only two possibilities remain, either (1) that the liver produces sugar from sources other than the glycogen originally present in it, or (2) that utilisation of sugar by the muscles and other tissues becomes suppressed.

It will be convenient at this stage to consider the

Puncture Diabetes.

Our problem, whether sugar production in the liver is under nerve control, thus narrows itself down to observing the behaviour of the blood-sugar curve following stimulation of the nerves and nerve centres which supply this organ. Let us in the first instance consider some of the results which have been obtained by such stimulation and later examine them in relationship to the other influences, such as those of a chemical (hormone) nature, which may exercise control over carbohydrate metabolism. In adopting this course, we are following historical precedent, since it was through the discovery, in 1849 by Claude Bernard, of puncture diabetes that the problem of the control of carbohydrate metabolism became susceptible to experimental investigation and, indeed, the whole field of experimental medicine was thrown open to the scientific explorer.

In his lectures on physiology delivered in 1855[3] this master experimentalist demonstrated on a rabbit the now famous piqûre experiment. He pushed a specially designed instrument through the cranium in the region of the occipital tuberosity, and directed its course so that it punctured the cerebellum and the floor of the fourth ventricle where the latter overlies the pons (between the roots of the eighth and tenth nerves). At the end of the lecture, urine, pressed out from the bladder, strongly reduced Fehling's solution.

This discovery of Bernard's was not haphazard. By comparing the reducing power of samples of blood taken from the portal and hepatic veins, he had previously obtained evidence that the liver secretes sugar, and the vagus appeared to him a probable nerve path for control of this function. Electrical stimulation of the vagus was not followed by glycosuria but this negative result did not daunt Bernard, for Magendie had previously observed that puncturing the origin of the fifth pair of nerves might excite the secretion of tears and saliva although this did not occur after their section. Bernard therefore asked himself the question, what would happen to sugar secretion after puncture of the floor of the fourth ventricle at the place of origin of the vagi. On subjecting this to the test of experiment, he obtained the results which we have just described. But these did not prove that the diabetogenic impulses were transmitted by the vagi. On the contrary, Bernard found when the piqûre was performed after cutting these nerves that the hyperglycæmia and glycosuria were no less pronounced than usual. When, on the other hand, the spinal cord was cut above the origin of the sympathetic fibres, piqûre became ineffective, indicating, so Bernard thought, that the diabetogenic centre must act on the liver through an efferent sympathetic pathway.

It is now recognised that disturbances anywhere in the nervous system may be followed by changes in the blood-sugar level, even psychic states, such as emotion, fright, and fear, being not infrequently associated with hyperglycæmia and glycosuria. Most anæsthetics have this effect, and among those commonly used the least disturbance in the blood-sugar level occurs with amytal (isoamyl ethyl barbituric acid) and other compounds of barbituric acid (Page [4]), although similar virtues have been claimed for chloralose. On this account, many of the recent researches in the control of carbohydrate metabolism have been performed on animals under amytal, and the practice has seemed to be further justified by the insignificant influence of this anæsthetic on the percentage of glycogen in the muscles (Cori [5]) and of lactic acid in the blood, both of which undergo considerable changes when other anæsthetics are used. It has always seemed to me that these inhibiting properties of amytal are against, rather than in favour of its use in experiments on carbohydrate metabolism. That this criticism is a valid one will be evident from the experiments done with Donhoffer,[6] which I shall now describe.

In rabbits anæsthetised by intraperitoneal injection of amytal or luminal, we performed piqûre in the neighbourhood of the vagus nucleus, either by Bernard's method through the skull or by Eckhard's, in which, prior to making the puncture, the floor of the fourth ventricle is exposed by opening the occipito-atlantoid membrane. In neither case did any increase occur in the blood-sugar level. This result impressed us all the more since I had previously found that when piqûre was performed by Bernard's method under local anæsthesia, hyperglycæmia invariably followed.

In view of the evidence which has recently been obtained of the presence in the region of the hypothalamus of a centre controlling the activities of the sympathetic nervous system (Karplus and Kriedl,[7] Houssay and Mollinelli,[8] Beattie, Brow, and Long [9]) the possibility had to be considered that this might be the chief diabetogenic centre and that its stimulation by puncture would induce hyperglycæmia even during the anæsthesia induced by amytal and luminal, since we had found that this occurred after injections of adrenaline into rabbits thus anæsthetised. We assumed that if the adrenal glands respond by secreting excess of adrenaline when the hypothalamus is stimulated, as is believed to be the case, this type of anæsthesia should not prevent the development of hyperglycæmia. In a considerable number of rabbits taken at random from the hutches, the brain was freely exposed by trephining, usually after ligation of both carotid arteries, and lesions which varied in severity from mere punctures to complete transections were made at different levels, with the result that the percentage of blood-sugar sometimes increased but without any relationship to the exact position of the lesion. The irregularity of the results offered little hope of our being able to achieve any success in localising a diabetogenic centre by such methods, and this became still more evident when it was found that pronounced hyperglycæmia might supervene in unoperated anæsthetised animals. This was noted especially when luminal was the anæsthetic used, although amytal did not always leave the blood-sugar undisturbed, as has been observed also by Underhill and Sprunt.[10]

It was evident that some other method would have to be followed in localising the centre. In deciding what this should be we were assisted by two important pieces of information, one being that hyperglycæmia often supervenes upon decerebration, and the other, that the anæsthetic effects of amytal in the rabbit quickly pass off when this drug is injected intravenously. The plan was, therefore, to perform decerebration while the animal was under intravenous amytal anæsthesia, and then to observe the behaviour of the blood-sugar in the decerebrated preparation after time had been allowed for the effects of the amytal to pass off.† The level of decerebration was varied in different experiments account for the hyperglycæmia. Even when we lect for this calculation the experiment on fasted imals which showed the most marked decrease in e percentage of glycogen, the glucose totals only 4 g., an amount which experiment has shown would ot appreciably affect the blood-sugar level when jected in solution intravenously into a rabbit over period of four hours.[6]

---

† Other anæsthetics, even though causing some hyperglycæmia, might also be used for the decerebration, an interval of time being then allowed to elapse for the blood-sugar to return to normal.

Blood Lactic Acid.

The percentage of lactic acid in the blood increases fter pontine decerebration, although this does not ccur to any significant extent after decerebration at ther levels. Average results are shown in Table V.

ABLE V.—*Average Percentages of Sugar and of Lactic Acid in Blood removed four hours after Decerebration.*

Position of ecerebration.	Blood-sugar per cent.	Lactic acid mg. per cent.	Expts. averaged.
I.	0·14	0·15	6
II.	0·14	0·39	2
III.	0·27	0·89	12
IV.	0·14	0·37	5

A similar increase in lactic acid also occurs, as Cori and Cori[17] have shown, when adrenaline is injected, but in this instance a closer parallelism was found to exist between the curves representing the changes in concentration of lactic acid and sugar than we found to be the case after decerebration.

Pontine decerebration, therefore, leads to an increase in lactic acid as well as in the sugar of the blood and to a diminution of the muscle glycogen, while the liver glycogen may either increase or decrease. In the normal fasting animal the liver must be regarded as a factory for glucose, using as its raw materials lactic acid, protein, and fat, and forming glycogen as a step in the process (gluconeogenesis), whereas the muscles act as a machine in which this glucose is condensed to glycogen which yields energy when it breaks down to lactic acid. What then causes the blood-sugar level to rise after decerebration? Is the excess of lactic acid primarily responsible for the increase in sugar, being converted into it by the liver; or is the accumulation of glucose in the arterial blood due to a disturbance in the process of its migration into the tissues? For although oxidation is not interfered with, the possibility remains that conversion of the glucose into muscle glycogen becomes retarded, so that diffusion from the blood is also retarded. This possibility receives support from the experiments of Cori and Cori[18] on adrenaline hyperglycæmia, with which the hyperglycæmia caused by decerebration has much in common. These workers show by measurement of the balances of free sugar and glycogen in the entire body and calculation of the carbohydrate combustion from the respiratory exchange, both in rats and rabbits, that over-production of sugar from the liver cannot account for the degree of hyperglycæmia which actually occurs, and they conclude that "the only possibility left is . . . that the animals injected with adrenaline are unable to utilise glucose at the same rate as normal uninjected animals."[14] In support of this interpretation it is pointed out that the difference in sugar concentration which normally exists in the blood as it enters and leaves the muscles becomes less marked or disappears altogether after adrenaline injection.

It might not require any considerable degree of suppression of glucose utilisation to raise the blood-sugar level, and it is possible that what really occurs, both in decerebration and adrenaline hyperglycæmia, is a slowing up in the rate at which the muscles form glycogen out of the blood-sugar. Glycogen disappearing from the muscle as lactic acid might in the liver be converted through glycogen into glucose, and as such be added to the circulating blood. A disturbance of this nature might not reveal itself by changes either in the respiratory metabolism of the muscles or in the glycogen content of the liver. Its only effect would be, as it were, to introduce a resistance into the migration of sugar from blood to tissues and so to raise the blood-sugar level and lower the glycogen level in the muscles.

I have already wandered far enough into the fields of speculation, but having gone so far I shall venture another step, by suggesting that the accumulation in the muscle of some substance intermediary between glucose and glycogen might be responsible for the possible delay in the migration of glucose from the blood. This would mean that we have to deal with something of the nature of a balanced reaction between the concentration of sugar in the blood and that of some carbohydrate derivative in the tissues.

Relationship Between Nervous Control and the Hormones.

ADRENALINE.

Having examined the nature of the disturbances in carbohydrate metabolism which are set up by decerebration, we are now led to compare them with those caused by the two hormones, adrenaline and insulin, which have effects which, in many ways, are mutually antagonistic. In almost every particular the changes in carbohydrate metabolism which are set up by adrenaline and by decerebration are strikingly alike. This suggests the possibility that the nerve impulses which decerebration engenders act primarily on the adrenal glands so as to cause an increased secretion of adrenaline into the blood. This suggestion is not new. It was put forward in 1906 by Mayer[19] with reference to piqûre, and it has led to innumerable researches dealing with the effect of adrenalectomy on the development of piqûre diabetes. Among more recent workers, Stewart and Rogoff,[20] have demonstrated that piqûre may still be effective in the absence of the adrenals. Other observers maintain that piqûre causes excessive amounts of adrenaline to be secreted into the blood. Evans, Tsai, and Young[16] have also shown that removal of the adrenals in cats has the effect not only of greatly diminishing the hyperglycæmia which follows decerebration but also of accelerating the rate at which glycogen reaccumulates in the liver after its disappearance due to the anæsthetic.

The foregoing evidence taken as a whole seems to show that although the adrenal glands must play some rôle in the development of piqûre hyperglycæmia, they are not essential to its occurrence. It is usually assumed that the impulses which excite the gland must reach it by the sympathetic (splanchnic) nerves and it is a fact, as Pearce and I found in the dog, that electrical stimulation of these nerves after adrenalectomy did not cause hyperglycæmia, as is the case in normal animals. On the other hand, hyperglycæmia occurred when the hepatic nerves were stimulated although, in this case, there could have been no excitement of the adrenal glands.

second of these possibilities: *diminished utilisation of sugar by the muscles.* As a first step in this utilisation sugar must pass from the blood plasma into the tissues, and it would appear that the rate of this migration is determined solely by the relative concentrations of sugar in blood plasma and tissue fluid. Observations on the rate of diffusion of sugar into muscle by comparisons of the percentages of free sugar in tissues and in blood plasma support this view (Cori, &c.[13]). Very shortly after entering the tissues the sugar disappears as such, being converted into glycogen and ultimately into lactic acid, although some may be directly oxidised, as evidenced by the rise in respiratory quotient which occurs in eviscerated animals when excess of sugar is present in the blood along with insulin. Other intermediary substances such as hexose phosphates are formed in this process, but the problem of their formation does not concern us now. What we wish to know is whether changes occur in the rate of utilisation of sugar in the tissues, and in the light of present knowledge we may form a rough estimate of this by measurement of changes in: (1) the respiratory exchange, (2) the glycogen content of the muscles, (3) their lactic acid production. Let me refer briefly to the results of measurements of these in rabbits decerebrated at various levels.

The Respiratory Exchange.

The problem was to find whether the consumption of O_2 and the respiratory quotient are affected by pontine decerebration in such a manner as to indicate, in comparison with their behaviour before decerebration, that there is diminished oxidation of carbohydrate. The Douglas bag method was employed, and the procedure finally adopted was to make two respiratory observations, an hour apart, after performing all the necessary operations except actually decerebrating. The average of these two results was then compared with the results obtained after decerebration, and it was found, in four out of six technically flawless experiments, that there was no significant change either in the O_2 consumption or the respiratory quotients (Table III.).

TABLE III.—*Average Consumption of O_2 and Average Respiratory Quotient before and after Pontine Decerebration.*

—	Before decerebration.		After decerebration.	
	O_2 c.cm. per kg. and hr.	R.Q.	O_2 c.cm. per kg. and hr.	R.Q.
1	420	0·73	482	0·75
2	278	0·87	373	0·82
3	291	0·78	287	0·89
4	397	0·91	347	0·91
5	390	0·95	382	0·94
6	404	0·83	423	0·86

From this we may conclude that diminished oxidation of carbohydrate in the muscles cannot be responsible for the accumulation of sugar in the blood. The results would at first sight also seem to contradict the view, which we will examine more fully later, that increased secretion of adrenaline is the immediate cause of the hyperglycæmia. But closer examination makes it doubtful if they are of significance in this connexion. For although adrenaline may have a calorigenic effect, the minimal rate at which it must be injected intravenously to cause it in the rabbit is 0·00025 mg. per kg. body-weight per minute, whereas one-fifth of this dose (0·00005 mg.) is capable of causing hyperglycæmia (cf. Cori[14]).

Glycogen Content of the Muscles.

I need not remind you that very great care must be taken in determining the glycogen content of mammalian muscle. Taking every known precaution, Donhoffer and I found that the glycogen content of the muscles of one leg removed before pontine decerebration was markedly greater than that of the muscles of the other leg removed several hours after it. Table IV., which also includes the changes in liver glycogen, will illustrate the results.

TABLE IV.—*Averages of Glycogen Percentages in Liver and Muscles before and four hours after Decerebration at Various Levels of Brain.*

—	State of animal.	Level of decn.	Liver.		Muscles.		Observations.
			Before	After	Before	After	
1	Fasting.	III.	0·93	0·68	0·32	0·23	11
2	Fed.	III.	6·41	2·90	0·67	0·50	6
3	Fasting.	I.	1·69	1·48	0·55	0·45	3
4	Fed and fasting.	II.	5·80	5·20	0·36	0·35	2
5	,, ,,	IV.	2·17	2·11	0·29	0·36	7
6	Amytal.	—	—	—	0·50	0·45	1

In No. 1 about 0·12 g. glucose per kg. and hr. set free from preformed glycogen; in No. 2, about 0·6 g. It requires 2·0 g. glucose per kg. and hr. injected intravenously to raise blood-sugar to 0·300 per cent.

In view of the effect of amytal alone we are probably safe in considering a change of ±0·05 in the percentage of muscle glycogen of no significance. When decerebration was anterior to the pons (positions I. and II.), although no increase in blood-sugar occurred, somewhat more glycogen disappeared from the muscles than after amytal alone, but it is possible that this was owing to the reflex movements which are common after decerebration at higher levels. When region IV., the medulla, was involved the muscle glycogen increased slightly but this is unusual, others having found that it remains unchanged in the spinal animal (Best, Dale, et al.[15]; Evans, Tsai, and Young[16]). In animals decerebrated at the pons, on the other hand, there was a decided reduction in the percentage of muscle glycogen, and this was especially marked in those animals in which the initial percentages were high because of previous feeding with carbohydrates.

This diminution in glycogen may to a certain extent have been due to retardation of its rate of formation out of blood-sugar, but the question also arises whether the portion which disappeared may not, by its addition as glucose to the blood, account for the hyperglycæmia. For although it is now well established that this muscle glycogen is not directly converted into glucose but into lactic acid, it is possible that the latter might become converted into sugar by being carried in the venous blood to the liver where such conversion is known to take place. It becomes of interest therefore to calculate whether sugar was mobilised from both the liver and the total musculature of the body in quantities sufficient account for the hyperglycæmia. Even when we ect for this calculation the experiment on fasted imals which showed the most marked decrease in e percentage of glycogen, the glucose totals only 4 g., an amount which experiment has shown would t appreciably affect the blood-sugar level when jected in solution intravenously into a rabbit over period of four hours.[6]

Blood Lactic Acid.

The percentage of lactic acid in the blood increases ter pontine decerebration, although this does not ccur to any significant extent after decerebration at ther levels. Average results are shown in Table V.

ABLE V.—*Average Percentages of Sugar and of Lactic Acid in Blood removed four hours after Decerebration.*

Position of cerebration.	Blood-sugar per cent.	Lactic acid mg. per cent.	Expts. averaged.
I.	0·14	0·15	6
II.	0·14	0·39	2
III.	0·27	0·89	12
IV.	0·14	0 37	5

A similar increase in lactic acid also occurs, as Cori and Cori[17] have shown, when adrenaline is injected, but in this instance a closer parallelism was found to exist between the curves representing the changes in concentration of lactic acid and sugar than we found to be the case after decerebration.

Pontine decerebration, therefore, leads to an increase in lactic acid as well as in the sugar of the blood and to a diminution of the muscle glycogen, while the liver glycogen may either increase or decrease. In the normal fasting animal the liver must be regarded as a factory for glucose, using as its raw materials lactic acid, protein, and fat, and forming glycogen as a step in the process (gluconeogenesis), whereas the muscles act as a machine in which this glucose is condensed to glycogen which yields energy when it breaks down to lactic acid. What then causes the blood-sugar level to rise after decerebration? Is the excess of lactic acid primarily responsible for the increase in sugar, being converted into it by the liver; or is the accumulation of glucose in the arterial blood due to a disturbance in the process of its migration into the tissues? For although oxidation is not interfered with, the possibility remains that conversion of the glucose into muscle glycogen becomes retarded, so that diffusion from the blood is also retarded. This possibility receives support from the experiments of Cori and Cori[18] on adrenaline hyperglycæmia, with which the hyperglycæmia caused by decerebration has much in common. These workers show by measurement of the balances of free sugar and glycogen in the entire body and calculation of the carbohydrate combustion from the respiratory exchange, both in rats and rabbits, that over-production of sugar from the liver cannot account for the degree of hyperglycæmia which actually occurs, and they conclude that "the only possibility left is . . . that the animals injected with adrenaline are unable to utilise glucose at the same rate as normal uninjected animals."[14] In support of this interpretation it is pointed out that the difference in sugar concentration which normally exists in the blood as it enters and leaves the muscles becomes less marked or disappears altogether after adrenaline injection.

It might not require any considerable degree of suppression of glucose utilisation to raise the blood-sugar level, and it is possible that what really occurs, both in decerebration and adrenaline hyperglycæmia, is a slowing up in the rate at which the muscles form glycogen out of the blood-sugar. Glycogen disappearing from the muscle as lactic acid might in the liver be converted through glycogen into glucose, and as such be added to the circulating blood. A disturbance of this nature might not reveal itself by changes either in the respiratory metabolism of the muscles or in the glycogen content of the liver. Its only effect would be, as it were, to introduce a resistance into the migration of sugar from blood to tissues and so to raise the blood-sugar level and lower the glycogen level in the muscles.

I have already wandered far enough into the fields of speculation, but having gone so far I shall venture another step, by suggesting that the accumulation in the muscle of some substance intermediary between glucose and glycogen might be responsible for the possible delay in the migration of glucose from the blood. This would mean that we have to deal with something of the nature of a balanced reaction between the concentration of sugar in the blood and that of some carbohydrate derivative in the tissues.

Relationship Between Nervous Control and the Hormones.

ADRENALINE.

Having examined the nature of the disturbances in carbohydrate metabolism which are set up by decerebration, we are now led to compare them with those caused by the two hormones, adrenaline and insulin, which have effects which, in many ways, are mutually antagonistic. In almost every particular the changes in carbohydrate metabolism which are set up by adrenaline and by decerebration are strikingly alike. This suggests the possibility that the nerve impulses which decerebration engenders act primarily on the adrenal glands so as to cause an increased secretion of adrenaline into the blood. This suggestion is not new. It was put forward in 1906 by Mayer[19] with reference to piqûre, and it has led to innumerable researches dealing with the effect of adrenalectomy on the development of piqûre diabetes. Among more recent workers, Stewart and Rogoff,[20] have demonstrated that piqûre may still be effective in the absence of the adrenals. Other observers maintain that piqûre causes excessive amounts of adrenaline to be secreted into the blood. Evans, Tsai, and Young[16] have also shown that removal of the adrenals in cats has the effect not only of greatly diminishing the hyperglycæmia which follows decerebration but also of accelerating the rate at which glycogen reaccumulates in the liver after its disappearance due to the anæsthetic.

The foregoing evidence taken as a whole seems to show that although the adrenal glands must play some rôle in the development of piqûre hyperglycæmia, they are not essential to its occurrence. It is usually assumed that the impulses which excite the gland must reach it by the sympathetic (splanchnic) nerves and it is a fact, as Pearce and I found in the dog, that electrical stimulation of these nerves after adrenalectomy did not cause hyperglycæmia, as is the case in normal animals. On the other hand, hyperglycæmia occurred when the hepatic nerves were stimulated although, in this case, there could have been no excitement of the adrenal glands.

For reasons which I do not propose to detail here we came to the conclusion that when there is widespread stimulation of the sympathetic system, the nerve stimulus set up is reinforced in its effects by a concomitant secretion of adrenaline. It is possible that this also occurs after decerebration or piqûre.

Donhoffer and I have also studied the effect of pontine decerebration in animals from which the adrenals had been removed several days previously. Typical results are shown in Table VI. In four animals in which the liver glycogen was 2 per cent. or less the blood-sugar did not rise, and there was little change in the glycogen content of liver and muscles; but in one in which about 5 per cent. was present hyperglycæmia was decided and considerable quantities of glycogen disappeared. This is the most interesting of the results, and when taken in conjunction with those of Stewart and Rogoff would seem to justify the conclusion that the presence of the adrenals is not *essential* to the development of hyperglycæmia after decerebration or piqûre, or to the rapid glycogenolysis which it usually sets up, especially in the muscles. Further observations on glycogen-rich animals are necessary before this can be accepted as final. The results obtained however do show that the presence of the adrenals makes the animal much more sensitive to the effects of decerebration, and we must suppose that this is because adrenaline is secreted in excess at the same time that the hepatic nerves are stimulated.

TABLE VI.—*Influence of Adrenalectomy on the Effects of Pontine Decerebration.*

Two Typical Experiments.

Insulin.

Antagonistic to adrenaline is insulin; but there is a fundamental difference in the scope of action of the two hormones, that of insulin being apparently restricted to carbohydrate metabolism, whilst that of adrenaline is widespread, affecting every function controlled by the sympathetic nervous system. Insulin is essential to the maintenance of a normal blood-sugar level, and its absence from the body is incompatible with life. Adrenaline, on the other hand, may apparently be dispensed with, since in its absence, as in completely adrenalectomised animals kept alive by repeated injections of extracts of the adrenal cortex, the blood-sugar is at or only slightly below the normal level.‡

I need not here describe the physiological and therapeutic effects of insulin. What interests us at present is that the maintenance of the blood-sugar at a practically constant level, not only under basal conditions but also when the demands for carbohydrate by the muscles are greatly increased, as during exercise, indicates that the secretion of the isles of Langerhans must be very delicately adjusted to the requirements of the organism, and the question arises as to how the control is mediated. Do the cells of the islets adjust their discharge of insulin according to the concentration of glucose or one of its derivatives in the blood circulating through them, or are they acted on by some other hormone, the presence or the concentration of which is related to the sugar concentration, or is the adjustment mediated through the nervous system? This problem is occupying the attention of many workers at the present time, and experimental results have already been obtained which are considered to support the latter or neurogenic hypothesis. I cannot deal with these results further than to state that they are considered to indicate that increase in the blood-sugar concentration excites some centre in the brain which then discharges, through the vagus nerves, impulses increasing the secretion of insulin. Although the cross-circulation experiments of La Barre and his collaborators,[21] upon which this important conclusion depends seem to be convincing, it must be pointed out that the results await confirmation, especially by methods in which the concentration of insulin, instead of being inferred from the behaviour of the blood-sugar level, is actually measured in the blood coming from the pancreas.

But even if the secretion of insulin is controlled by the vagus nerve it does not seem likely that this can be the only means by which the nervous system exercises control over carbohydrate metabolism, for it is impossible to accept the view that decerebration hyperglycæmia could be due to a sudden cessation in this secretion. When the secretion stops, as a result of pancreatectomy, for example, it is not until some hours have elapsed that the blood-sugar rises to levels comparable with those reached after decerebration, and it is scarcely likely that this operation could lead to the discharge of impulses causing complete inhibition of the insular secretion. It is true that Clark [22] has brought forward evidence showing that the assimilation curve following the intravenous administration of glucose may be depressed in vagotomised rabbits. This would seem to indicate that inhibitory impulses are transmitted by the vagi, but even if the discharge of these should be so violently stimulated by decerebration as to bring about entire cessation of the secretion of insulin, it would presumably take some time before the hyperglycæmic effects would show themselves.

Taking the available evidence as a whole, increased secretion of adrenaline would appear to play a more important rôle in causing the hyperglycæmia and the other changes in carbohydrate metabolism which follow decerebration than would a sudden suppression in the secretion of insulin. It is now well established that much smaller concentrations of adrenaline are required to raise the blood-sugar level than to raise the blood pressure or the basal metabolism, and when we remember that sugar production by the liver is also under direct nerve control, it is quite likely that the impulses set up by decerebration act in part on the liver and in part on the adrenal secretion. It is possible, of course, that the combined effects of these two changes are amplified by a diminution in the internal secretion of insulin, although for this we have at present no evidence.

These considerations lead us to inquire whether the balance existing between the effects of these two mutually antagonistic hormones, adrenaline and insulin, may be what primarily determines the state of carbohydrate metabolism in the normal animal, rôle of the nervous system being mainly con- ıed with the immediate and rapid changes in the ıply of sugar by the liver required during muscular ivity.

---

‡ It is possible, however, that these cortical extracts always contain traces of adrenaline.

continued preponderance in the concentration adrenaline has been suggested as the fundamental ıse of the diabetic state. In discussing this prob- ı some years ago, I was inclined to accept the w, advanced especially by Stewart and Rogoff,[23] it this explanation is untenable, but if we recon- er it on the assumption that it might require only slight preponderance of adrenaline over insulin, ing continuously, as would be the case when the retion of insulin is curtailed, I am by no means certain that it can be summarily dismissed.

The recent discovery of methods by which the fatal ects of adrenalectomy may be counteracted by ection of extract of the adrenal cortex may open the opportunity of subjecting this problem to e test of direct experiment. We are as yet far m understanding the underlying cause of diabetes, although all the known facts regarding this disease nform with the definition that it is one in which ere is a certain degree of deficiency of insulin in e organism, we are still left with the problem of counting for the over-production of sugar and the her metabolic disturbances which characterise it.

ffect on Nervous Hyperglycæmia of Interference with the Efferent Pathway by Section and by Drugs.

We have seen that there are several ways by which ıe nervous system might bring about a rise in blood- ıgar, and it may be of advantage to recapitulate ıose we have so far considered. They are :

1. Stimulation through the hepatic nerves of the break-)wn of glycogen already present in the liver or of the ocess of gluconeogenesis in this organ.
2. Stimulation of the internal secretion of adrenaline.
3. Inhibition of the internal secretion of insulin.

timulation through the hepatic nerves leaves out of ccount any effect on the breakdown of glycogen in he muscles, so that, at best, it could only partly xplain the changes which accompany decerebration yperglycæmia, but if, at the same time, either or oth of the humoral effects come into play all the bserved changes would be satisfactorily accounted or. The actual amount of adrenaline secreted need ıot necessarily be large if it is accompanied by a imultaneous cessation in the secretion of insulin. The possibilities which these considerations suggest nay be put to the test of experiment by blocking, ither by section or by drugs, the nervous pathways long which the impulses that control the various unctions must travel.

According to present-day knowledge, the most ikely efferent nerve pathways are the sympathetic splanchnic) to the adrenal glands and liver, and the parasympathetic (vagus) to the islands of Langerhans. The possibility also exists that the stimulus which sets up glycogenolysis in the muscles is carried by somatic autonomic nerves, the only other alternative being that the activity of this process is solely dependent upon the presence of hormones. These considerations suggest various experiments, which Donhoffer and I have tried. We found, after section of the vagi in the neck, in fasting rabbits, that decerebration did not cause the usual degree of hyperglycæmia. Thus the blood-sugar rose only to 0·156 per cent. in two hours in one such animal, and to 0·226 per cent. in four hours in another. Assuming this effect of vagotomy to be owing to severance of the parasympathetic pathway to the liver, we next tried the effect of more complete blockage by combining vagotomy with the injection of atropine (1·0 mg. followed at intervals by 0·5 mg.). In five out of six experiments of this type the blood-sugar in three or four hours after decerebration did not rise to anything like the extent usually observed, but in the remaining animal the rise was very pronounced. I mention this detail because it so happened that this was the only animal of the series in which the glycogen content of the liver was determined, nearly 4 per cent. being found. This is a high percentage for an animal that has been fasted over night, and the result suggested the possibility that the hyperglycæmia had failed to develop in the other animals because only small amounts of liver glycogen were present. In a further series of five experiments, partly on fasted and partly on richly fed rabbits, glycogen was accordingly determined, both in liver and muscles, at the beginning and end of the experiments. The results are seen in Table VII.

* Glycogen unknown.

We may explain these results by assuming that when the liver contains only the glycogen which is left over as a by-product of gluconeogenesis, severance of the parasympathetic pathway renders decerebration ineffective in exciting an increased sugar discharge, but does not do so when the organ is heavily loaded with glycogen formed and stored up in it from absorbed carbohydrate. The behaviour of the muscle glycogen was much the same in the two groups of animals, and may therefore for the moment be left out of consideration. What the results do seem to indicate is that, in a physiological sense, two kinds of glycogen may occur in the liver, the one associated with the process of gluconeogenesis—perhaps as a sort of by-product—which is under parasympathetic nerve control, and the other merely a storage form for glucose into which it may be reconverted through other influences.

In view of the effect of ergotamine in blocking the motor myoneural junctions of the sympathetic, its effect on decerebration hyperglycæmia was studied, with the hope that it might prevent breakdown of the storage form of glycogen, but this is *not* the case. It seems to act much like atropine. Thus, in two experiments on fasted rabbits with only traces of liver glycogen, the injection of 0·5 mg. of ergotamine just prior to decerebration prevented the usual rise in blood-sugar.

When both atropine and ergotamine were given and the vagi cut as well, pontine decerebration had no effect on the blood-sugar level unless when large amounts of storage glycogen were present in the liver (Table VIII.). In an experiment, for example, on an animal in which the liver contained 7·9 per cent. glycogen and the muscles 1·13 per cent., the blood-sugar rose to 0·485 per cent. three hours following decerebration, and there were marked losses in glycogen in both tissues. To account for the hyperglycæmia under these conditions we must assume either that hypersecretion of adrenaline has occurred as a result of stimulation through some nerve pathway which neither atropine nor ergotamine can effect, or that the glycogenolysis is set up by the vascular disturbance which, to judge from the congestion of the *abdominal* blood-vessels, *constantly* follows piqûre or decerebration.

TABLE VIII.—*Influence of Ergotamine, and of this plus Atropine, on Blood-sugar and Glycogen Percentages following Pontine Decerebration.*

a = Amytal injected.

I have laid before you these perplexing facts in order to indicate that we do not consider that demonstration of the relationship of the vagus to *decerebration hyperglycæmia does any more than* reopen the problem of the nerve control of carbohydrate metabolism. The one thing that is established is that blockage of the parasympathetic pathway prevents hyperglycæmia from developing when traces only of glycogen are present in the liver.

Action of Amytal and Other Barbituric Acid Derivatives.

There remain two other experimental findings to which I should like in concluding to call attention. The one is that amytal has exactly the same influence on decerebration hyperglycæmia as atropine, the hyperglycæmia being inhibited in fasted rabbits by its injection. Hence the confusion in the results of our earlier experiments in which amytal and luminal were the anæsthetics used. This effect is not surprising when we recall that, in animals under amytal, stimulation of the vagus fails to cause cardiac inhibition, and it may be added that stimulation of the chorda tympani causes much less than the usual secretion of saliva from the submaxillary gland. The drug evidently has a paralysing effect on the parasympathetic nervous system.

The other interesting fact is that atropine and ergotamine greatly diminish or entirely prevent the rise in the blood-sugar level which ordinarily follows the ingestion of sugar. This effect is not seen when the sugar is given intravenously, which suggests that it is possibly caused by an interference with absorption. This explanation is, however, not accepted by those who have studied the problem (Allard,[24] Pollak [25]). Although I can offer no explanation of the phenomenon, it is unquestionably of some significance that the drugs should have similar effects on both decerebration and alimentary hyperglycæmia.

But here I must stop, leaving unanswered the question with which we started, concerning the coördination between the requirements of the muscles for sugar and its rate of supply by the liver. From the evidence at present available it may be justifiable *to postulate that when the requirements are* more or less steady, the rate of sugar production is regulated by alterations in the balance between insulin and adrenaline in the blood, but when there is a sudden call for sugar to meet the demands of *great muscular activity direct* nervous stimulation of sugar secretion by the liver is set up. As to how the balance between insulin and adrenaline is adjusted, it is possible since the secretion of each of these hormones is subject to nerve control, that the sugar concentration of the blood supplying the nerve centres is the stimulus which acts on them. In the light of the experiments which I have described, these centres are probably situated somewhere in the pons, and the discharge of impulses from them, which is set up by decerebration, acts in such a way, as to cause increase in the secretion of adrenaline, and decrease in that of insulin, at the same time that *glucose secretory impulses are* discharged to the liver.

SHEFFIELD ROYAL HOSPITAL.—It is announced that £25,000 is to be given to this hospital by miners' welfare committees in South Yorkshire for the equipment of a new X ray department. A centenary appeal for £100,000 was recently launched by the hospital to meet an overdraft of £60,000 at the bank and to carry out improvements urgently required.

ECTION OF THE UMBILICAL VEIN IN RETAINED PLACENTA.

DAVID W. CURRIE, CH.M. LEEDS, F.R.C.S. ENG.,
TUTOR IN GYNÆCOLOGY AND OBSTETRICS IN THE UNIVERSITY OF LEEDS.

ANY of the dangerous complications of pregnancy the first two stages of labour can now be foreseen, due provision can be made for them. But the ical attendant is still unable to foretell what occur during the third stage.

etention (either partial or complete) of the enta is a common cause of post-partum hæmorge and strongly predisposes to puerperal infection. h retention necessitates in the first instance a lé's manœuvre with its associated shock; should fail the surgeon is compelled to undertake manual oval, a procedure performed outside the protecting ıg of the fœtal membranes and not completed hout further serious hæmorrhage.

he term "retained placenta" implies that the enta is lying unattached in the cavity of the rus and that its expulsion has not been effected ause of some abnormality; this abnormality y be either atony of the uterus following a longed labour or hour-glass contraction or pressure a full bladder. On the other hand the placenta y remain adherent, either partially or completely, hout showing any pathological cause. Totally ıerent placenta is in fact much rarer than is ıally believed: this group includes placenta reta and increta, neither of which concern us in present discussion, since they do not give rise alarming hæmorrhage or demand specialised atment.

It is convenient at this stage to summarise the ocedure adopted in the Leeds Maternity Hospital the conduct of the third stage of labour. mediately after the delivery of the child the tient is turned on her back and the cord is placed a sterile dish between her thighs. The height the fundus is noticed but the uterus is not touched less undue loss of blood necessitates the use of ntle massage to induce a contraction. In most ses the patient is left undisturbed for twenty inutes, except that the height of the fundus is served from time to time, also the presence of emorrhage. In normal cases the simple tests for e position of the placenta are made (lengthening shortening of the cord, the height of the fundus, ape, contour, and mobility of the body of the erus). If such tests reveal that the placenta is ing in the lower segment or vaginal vault, the ndus is massaged to elicit a contraction and the terus is then used as a piston to push the placenta ut of the vagina. If the tests show that the placenta as not left the uterus they are repeated at intervals f five minutes. No alarm need be felt if the placenta retained without hæmorrhage, but should the lacenta be retained and a post-partum hæmorrhage ccur this will continue until the placenta is removed nd the uterus made to contract evenly; in these ases the accoucheur's hand is forced and he is ompelled to aid the delivery of the placenta.

MANUAL REMOVAL AND ITS DANGERS.

It was formerly the custom to attempt to express he placenta by means of Credé's manœuvre, and hould this be unsuccessful to repeat the manœuvre t intervals and under an anæsthetic if necessary before resorting to the dangerous manipulation of manual removal. It must not be thought that Credé's manœuvre itself is not dangerous; the shock induced by severe compression of the uterus through the abdominal wall may result in the collapse of the patient, especially if she has lost much blood and has been sent to hospital from a considerable distance. There is in addition the possibility of tearing the placenta resulting in one or more cotyledons being left in situ.

Manual removal of the placenta is usually an easy operation because of the undoubted fact that placentæ remaining in the uterus are as a rule partially or totally separated from the uterine wall; but statistics show that the accompanying morbidity- and mortality-rates are extremely high. Thus Bourne[1] gives the figure for morbidity at 35 per cent., and Goethals[2] at 39·4 per cent. The death-rate varies from 7 per cent. to 10 per cent. according to different observers, hæmorrhage seeming to account for rather more than half the fatalities. Goethals mentions in his paper the records of the Boston Lying-in-Hospital, which show that manual removal was effected 170 times in 8182 cases with a death-rate of 8·2 per cent., brought down to 1·76 per cent. by missing out all the complicated cases. One in every four cases of removal showed signs of uterine infection according to the B.M.A. standard. The figures of Queen Charlotte's Hospital from 1906–1916 (omitting 1909, 1910, 1911, and 1915) show that the placenta was removed manually 154 times; 54 patients developed sapræmia (i.e., 35 per cent. became morbid) and there were five fatal cases, giving a mortality of 3·2 per cent.

During the last five years at the Leeds Maternity Hospital, the placenta has been removed on 87 occasions; 28 of the cases became morbid and 14 proved fatal. Two patients died before the placenta was delivered. This gives a morbidity-rate of 32·7 per cent. and death-rate of 16 per cent. It must be mentioned that these figures include a large number of emergencies, some of the patients being extremely ill on admission.

The dangers encountered are: (1) infection by micro-organisms, (2) hæmorrhage during and after the operation, (3) shock during the extraction, and (4) rupture of the uterus. The factors playing a part in the causation of sepsis are: (1) the introduction of micro-organisms, and (2) the resistance of the patient.

As previously mentioned, removal of the placenta with the membranes necessitates the introduction of the hand outside the membranes. That means the fingers come in contact with the raw placental site, where there are large open venous sinuses, likened by Bethel Solomons to incubator tubes awaiting inoculation. The micro-organisms may be carried in from outside or may be present already in the cervix and vagina. The resistance of the patient varies according to her general condition, and it is obvious that patients who have bled considerably or who have borne a long and tedious delivery probably terminated instrumentally are handicapped from the start.

The difficulty is to know how long to wait before embarking on manual removal. Goethals suggests that one should wait one hour and then try all other methods first. H. Germans[2] advises waiting from two hours onwards. In cases without hæmorrhage Polak[2] is content to leave the placenta in situ; in those with hæmorrhage he packs the uterus and the placenta with iodoform gauze which stops the hæmorrhage and eventually causes separation. It seems obvious to us that the time factor can only be taken into account in those cases without hæmorrhage, for when post-partum bleeding takes place during the third stage the indication for interference is rather the condition of the patient than the interval of time.

At this point it is interesting to mention a series of cases collected by Dr. Henry Bailey, of Horsforth (near Leeds). This consists of 23 instances of retention of the placenta, only one of which was associated with any severe degree of hæmorrhage. In all it was found impossible to obtain delivery of the placenta by manipulations short of a "Credé" under anæsthesia and so the patient was left with the placenta in situ. The placenta was delivered spontaneously after periods varying from five hours to six and a half days. Only one case showed signs of fever and that was one in which a forceps delivery had occurred with a perineal tear. These cases do not seem to agree with the findings of Hammerschlag, who says that after 24 hours the uterus becomes invaded with bacteria. However, by far the greater number of cases of retention are associated with hæmorrhage. In the previous paragraph I have recorded the statistics of manual removal and with these eloquent figures in mind we have during the past year been attempting to find some other less dangerous method of effecting the delivery of the placenta, and this we think we have found in a reconstruction of the Mojon-Gabaston treatment of injection of the umbilical vein.

MOJON-GABASTON TREATMENT.

My attention was drawn by Prof. A. M. Claye to a paper by Jarcho[3] where there is a history of the method and a description of three cases successfully treated by him. The history is briefly as follows.

Mojon in 1826 injected acidulated water into the umbilical vein and induced separation with subsequent delivery of the placenta. The result he thought to be due to (1) the sudden increase of pressure at the placental site, (2) cold transmitted to the placental site. Legros in 1828 found the method particularly efficacious in atonic bleeding. Basedow in 1829 tried the method several times and found it useless. Most in 1834 injected both veins in a case of twins. He said that the cold caused a cessation of bleeding and subsequent contraction of the uterus. Schwarz in 1835 reported good results not only in retention, but also in uterine hæmorrhage following partial separation. The method however fell into disuse because of the complete lack of aseptic precautions.

Koerting[4] reviewed the treatment in 1925, and came to the conclusion that injection of the vein makes a "Credé" unnecessary. He thinks that a previous "Credé" lessens the efficacy of the injection, but that after injection, removal by an easy "Credé" is usually successful. On the other hand he holds that in cases of profuse hæmorrhage injection is contra-indicated. This view was also expressed by Goethals, and if correct greatly lessens the value of the operation.

The technique as described by Jarcho is this. First one makes sure that the placenta is still in the uterus by using the simple tests, supplemented if necessary by a rectal examination. The requirements consist of a Record syringe, a large needle, and 200–300 c.cm. of sterile saline. The cord is thoroughly cleansed for about 8 inches near the vulva. This part of the cord is used because it is least likely to be soiled by fæces, and most likely to contain a patent umbilical vein. The saline is then slowly injected and the physician waits for the onset of uterine contractions and delivery of the placenta. This, in the three reported cases took place in 10–40 minutes.

In the summary at the end of the paper, Jarcho says: (1) The solution distends the placenta, ruptures the small veins, and forms a retroplacental hydroma, which by its mechanical action causes separation and expulsion of the placenta. (2) The method is simple. (3) No anæsthetic is needed. (4) No infection is carried to the uterus. (5) If delivery of the placenta is unsuccessful, injection makes a subsequent manual removal easy.

TEST OF THE METHOD.

The procedure used in this hospital has followed mainly that described by Jarcho; in the first few cases we used a large Record syringe, and injected the fluid slowly; the patient's pulse and blood pressure were noted before, during, and after the injection and were found not to alter. If, as Jarcho suggested, the separation of the placenta was caused by the tearing of the small veins, we thought that if the saline was injected faster there would be more likelihood of this occurring, and so the Record syringe was supplanted by Scannel's apparatus, and a large No. 20 needle introduced, such as is used for subcutaneous infusions.

Scannel's blood transfusion apparatus consists of a 20 c.cm. syringe with a three-way tap and thus overcomes the delay made necessary by the repeated disconnexion of the ordinary Record syringe. The patient is placed comfortably in bed with the lower part of the abdomen and thighs exposed, the thighs at the same time being abducted, the vulva and the surrounding skin and the cord are thoroughly cleansed with soap and biniodide spirit, and the cord placed on a sterile towel lying between the patient's legs. The needle is inserted into the umbilical vein about 6 inches from the vulva, and held in position by a ligature.

It is better to leave some undamaged cord between the needle and the vulva in case it is necessary to reinsert the needle. The injection of the saline is now commenced and it has been our aim to inject at the rate of 300 to 400 c.cm. in two and a half minutes. We have found that 350 c.cm. is about the average amount of fluid used. On completion of the injection an artery forceps is placed on the cord, the needle is removed, and the placenta is expressed if it has not been already spontaneously delivered. As the fluid enters the placenta the fundus of the uterus is felt to rise up in the abdomen and later strong uterine contractions occur. We have not deemed it necessary to await the spontaneous expulsion of the placenta but rather to aid its delivery by immediate expression, during a contraction, after the completion of the injection.

With the intention of testing the method thoroughly, most of the cases treated, and to be described, were submitted to the orthodox procedures in vogue for retention of the placenta. By this we mean that attempts at expression were made by means of a "Credé" first without, and later with an anæsthetic; and furthermore usually by more than one separate operator before injection was proceeded with. This means that the cases we have collected would all have terminated in manual removal had injection failed. What is more, according to Koerting we were deliberately jeopardising our chances of success by attempting removal by means of a "Credé" before injection.

Case Records.

Case 1.—Aged 37. Fifth pregnancy. Previous obstetrical history: (1) 3-months' abortion. (2) Normal full-time; forceps. Child stillborn (December, 1927); manual removal. (3) 3-months' abortion. (4) Normal full-time; forceps; child stillborn (August, 1930); manual removal. The Wassermann reaction had been investigated on two occasions and found to be negative.

Present pregnancy.—A living child was born naturally, premature by six weeks. The patient oozed continuously and one hour and twenty-five minutes later the placenta was still in situ. The blood pressure was 80 systolic and 50 diastolic. An attempt at "Credé" failed, and as the bleeding had momentarily *ceased, two pints of gum saline* were given, resulting in a marked increase in the blood pressure 128/60. 250 c.cm. of saline were injected by means of a Record syringe into the umbilical vein in an attempt to separate the placenta. The time for injection was 11½ minutes. There was no success, the fluid seemed to run back again alongside the cord. An anæsthetic was commenced and preparations made for manual removal. As a "Credé" under the anæsthetic proved useless, the placenta was finally removed manually.

This was a difficult operation, the placenta seemed to be firmly adherent to the uterine wall and had to be scraped away. It was pale, thin, and fibrous. On looking up the old notes it was found that a similar state of affairs had occurred in 1930. The patient was later given 20 oz. of citrated blood, *and made an uneventful recovery.*

This case is interesting in that it was the first of our series and our only failure. Her previous obstetrical history shows that she had had two abortions and two full-time difficult deliveries followed by manual removal; in neither of which had there been any suggestion of infection. The placenta was firmly adherent and in view of the later findings totally unsuited for removal by injection. The saline was injected very slowly, and was possibly given time to leak gradually away without distending the placenta.

Case 2.—Mrs. B., aged 30. Eighth pregnancy. Previous history: (1) and (2) Full-term. (3) Full-term; retained placenta; manual removal. (4), (5), and (6) Full-term. (7) Full-term; retained placenta; manual removal.

This patient was admitted in a precarious condition two hours after delivery of the baby. She was a heavy woman with œdema of the lower half of the body, solid albumin in the urine, and chronic mitral disease. The history was that she had lost continuously since the birth of the baby, and that abortive attempts at Credé's expression had been made. Her *pulse-rate on admission* was *104, B.P. 70/?,* she was cold, clammy, and gasping for air. The placenta was firmly fixed in the uterus near the fundus. The shock was treated with salines, morphia, and radiant heat; a blood donor being sent for. An attempt at a "Credé" without anæsthesia was unsuccessful.

300 c.cm. of saline were injected into the umbilical vein as rapidly as could be given, the fundus of the uterus rose in the abdomen, contractions were elicited, and the placenta was delivered into the vagina, and later pushed out into a dish. The hæmorrhage ceased and the uterus contracted well. Preparations were made for a transfusion, and this was about to be given 2½ hours later, when the patient suddenly collapsed *and died. Post-mortem examination* showed advanced myocardial degeneration. This is the only death in the series.

Case 3.—Aged 25. First pregnancy. This patient was delivered normally and continued to bleed slowly for 50 minutes, loss 1200 c.cm. An attempt at a "Credé" was unsuccessful. Preparations were then made for a manual removal and the patient anæsthetised. "Credé" was attempted under the anæsthetic but without success. 300 c.cm. of saline were injected into the umbilical vein. The uterus could be felt enlarging and contracting, the placenta being expelled with ease.

Case 4.—Aged 26. First pregnancy. Patient delivered normally but lost continuously all the time, so the fundus was controlled. As the bleeding continued, attempts were made to express the placenta using much force with both hands. The bleeding had by now amounted to 900 c.cm. in 20 minutes. 300 c.cm. of saline were injected, the time taken being two minutes. The uterus could be felt to be distending as the fluid ran in. An immediate attempt at expression had the desired result. The placenta was greyish-white in colour. There were no cotyledons. There were three hard white fibrous nodules 1 in. × 2 in., and at the edge was a band of fibrous tissue ¼ in. thick.

Case 5.—Aged 31. First pregnancy. Patient sent in as an emergency three hours after delivery with the placenta in utero following forceps extraction, with a complete perineal tear. The history of the pregnancy suggested placenta prævia. She had bled on three occasions, the last loss being profuse and occurring the day before delivery. On admission she was extremely collapsed, blanched, restless, almost pulseless, skin cold and clammy. Pulse-rate 164. Blood pressure 85/? No hæmorrhage per vaginam.

—	Blood pressure.	Pulse-rate.	—
On admission	85	Almost *pulseless.*	9 A.M.
After 1 pint saline ..	—	164	9.30–10 A.M.
	84	140	11 A.M.
After 1 pint blood ..	114–120	144–110	12 noon.

An examination was made per rectum. The vagina appeared to be empty except for what was thought to be placental tissue lying near the cervix. Abdominal tests showed the placenta to be mainly in the uterus. Only half an inch of the cord was available, the bulk having beeen torn off in attempts to obtain delivery. Mild attempts to press the placenta out of the uterus failed, and caused such extreme distress in her precarious condition that they were not persisted with. At 12.25 P.M. 300 c.cm. of saline were infused into the umbilical vein, the time taken being 2½ minutes. The placenta was expressed with ease. Even with this mild operation the patient collapsed again.

—	Blood pressure.	Pulse.	—
5 oz. blood*	80	150	—
15 oz. gum saline*..	118	116	1.30 P.M.
	110	140	4 P.M.
	110	140	6 P.M.
	110	138	8 P.M.

* As the veins were so collapsed it was found necessary to make an incision to locate one.

The placenta was large, one edge had drawn down in a long lip possibly by the head, and presumably this was the part felt in the vagina and the cause of the *ante-partum* hæmorrhage. The patient made an uneventful recovery.

Case 6.—Aged 20. Second pregnancy. Patient admitted before delivery following two abortive attempts at forceps delivery. Her condition was fair, except for an acute post-anæsthetic bronchitis. She had a small round pelvis and was having strong pains, the fœtus was dead. *Perforation* and craniotomy were undertaken under spinal anæsthesia, the perineum being torn; without any further delay the umbilical vein was injected, 300 c.cm. of saline being used, the placenta obtained and a perineal repair subsequently undertaken.

Although there was no suggestion of retained placenta in this case, it shows two valuable uses of the treatment.

(1) If the patient has bled before delivery, or has undergone difficult instrumentation, so that further loss of blood would make her condition dangerous, the accoucheur has a means at his disposal of obtaining the placenta at once. This has been undertaken with success on four occasions.

(2) In cases of severe lacerations of the vagina, which, if sutured whilst the placenta is still in utero and are liable to break down again during its delivery, the placenta may be obtained at once and the danger overcome; also the field of vision is not obscured by escaping blood lost during the normal separation of the placenta.

Case 7.—Aged 32. Fourth pregnancy. Admitted as an impacted labour. Small pelvis, large child weighing over 11 pounds. No fœtal heart heard. The later weeks of the pregnancy had been complicated by pyelitis with associated rigors. She had been three days in labour and the vaginal discharge was very offensive. Delivery was effected after perforation and *craniotomy* with a bilateral cleidotomy. At the end of 30 minutes the placenta was still in utero, there had been a continuous loss of blood, the blood pressure had fallen to 90/60. Attempts at a "Credé" were undertaken, the patient being still under the anæsthetic and although it was possible to obtain a good grip of the uterus they were unsuccessful. 300 c.cm. of saline were infused and the placenta easily expressed. One pint gum saline given, B.P. 115/70.

This case was successful, especially in view of the fact that the patient had been in labour many days, there was a foul discharge and an excessive amount of internal manipulation. The dangerous operation of manual removal was thus much to be avoided.

CASE 8.—Aged 27. First pregnancy. Forceps applied for primary uterine inertia. One hour after the delivery of the child the placenta was still in utero. She had lost 900 c.cm. of blood. "Credé" was attempted, the patient being still under the influence of hyoscine. This was not successful, the uterus was difficult to grasp as it seemed to have become acutely retroverted. 300 c.cm. of saline were injected and the placenta obtained. This patient had been treated during pregnancy for a vaginal discharge.

CASE 9.—First pregnancy. Admitted with the head delivered. The child was a macerated and peeling hydrocephalic monster. The placenta was still in utero at the end of four hours, the patient's condition being good, as there had been no bleeding. It was difficult to ascertain the position of the placenta by abdominal palpation because of the extraordinary tenseness of the abdominal walls. The fundus did not reach to the umbilicus, it was broader than long and examination per rectum showed the vagina to be empty. Attempts to obtain a grasp of the uterus were impossible owing to the muscular rigidity.

The cord was soft and discoloured. The vein was isolated by dissection and injection commenced; after the injection of 280 c.cm. the patient had strong uterine contractions, strong enough to make her wince and the placenta was literally shot out of the uterus into the bed.

The placenta was small, 13×10 c.cm., pinkish-white, without any cotyledons. There were numerous white nodules which appeared to be encapsulated, and these on section showed as fibrous nodules with a central core resembling old blood and serum. The placenta was reported by the pathological department to show numerous areas of necrosis with granules of calcification. The Wassermann reaction was negative.

CASE 10.—Aged 28. Third pregnancy. Admitted with a history of bleeding for three days following a severe fall on the previous day. She was complaining of abdominal pain located in the left loin and iliac regions. Pulse-rate 102. Temperature 101°. Urine clear. Examination of the abdomen suggested a five months' pregnancy. Delivery of a macerated fœtus occurred a day later, a large quantity of old and new blood followed the completion of the second stage, the patient's temperature being then 103°, pulse-rate 136. After a lapse of 40 minutes the placenta showed no signs of separation and unsuccessful attempts at delivery were made by Credé's manœuvre with and without an anæsthetic. The fundus was difficult to locate because of the small size of the uterus. 150 c.cm. of saline were injected in 90 seconds into the vein, and the fundus rose in the abdomen so that it was an easy matter to grasp it, and easily expel the placenta. The placenta was small and fibrous, whitish-pink in colour, and covered with old blood clot.

This case was the third attempt to obtain a placenta retained in utero after an abortion and the only one to be successful.

CASE 11.—Aged 19. First pregnancy. Normal delivery. Ten minutes after delivery the patient began to lose considerably and continuously. After 30 minutes the placenta still being unseparated a "Credé" manipulation was attempted firstly without and then with an anæsthetic. This was not successful, but success followed the injection of 400 c.cm. of saline. The patient lost 1400 c.cm. of blood before the placenta was obtained. Wassermann reaction positive.

CASE 12.—Aged 35. Seventh pregnancy. Admitted as a prolonged labour. Patient very stout with pendulous abdomen. Delivery was normal, but the uterus failed to contract after the birth of the child and the patient lost slowly. "Credé" tried without effect. 450 c.cm. of saline were injected into the umbilical vein and we waited for 10 minutes in the hope that uterine contractions would commence. As these were not forthcoming another 400 c.cm. were injected. This second injection induced strong contractions associated with uncontrolled bearing down, resulting in the delivery of the placenta. Patient had lost 1500 c.cm.

CASE 13.—Aged 32. First pregnancy. General condition poor. The birth of the child was effected by forceps following a prolonged labour. The patient bled freely, the uterus appearing to contract well but not to completely separate the placenta. A "Credé" under anæsthesia proved unsuccessful. 320 c.cm. of saline were injected into the umbilical vein and the placenta easily expressed. The placenta was small and thick. There were numerous cotyledons distinctly separated from each other, the depressions being wide enough to show the maternal surface of the fœtal membranes.

AN INVESTIGATION INTO THE MECHANISM OF DELIVERY.

Of the various causes to which the success of this injection was attributed, I think that the increase of bulk is the first and foremost. When the method was first instituted it was suggested that the temperature of the acidulated water was the main feature. The cold water caused a cessation of the hæmorrhage, and a renewal or increase in power of the uterine contractions effected the birth of the placenta. The theory put forward by Jarcho in his paper was that the injected fluid gradually found its way to the smaller vessels of the villi and bursting through the villi formed a hydroma between the maternal decidua and the placenta. This separated part of the placenta and induced uterine contractions. The hydroma then acted in the same way as the retroplacental hæmatoma and was squeezed from out of the uterus, separating more of the placenta on its way.

It was with the express desire of causing a rupture of the small veins of the placenta that I injected the saline as fast as possible rather than slowly and the results seemed to substantiate this view by the fact that separation and delivery were easily obtained. It was noticed, however, upon using coloured saline, that no saline ran away from the vulva until after the completion of the third stage—a fact that seemed difficult to explain if a retroplacental hydroma formed; even supposing that all the deliveries followed Schulze's mechanism.

One hundred and two normally evacuated placentæ were obtained immediately after birth and examined. They were then subjected to injection; it was found that on an average a placenta would accommodate 350 c.cm. of fluid before leakage occurred, and that when it did occur the fluid escaped rather at the periphery of the placenta than from the centre. This means that if the placenta in utero will hold the same quantity of fluid as the delivered placenta, few of our cases were subjected to a pressure great enough to burst the small veins and no retroplacental hydroma was formed.

DISCUSSION OF RESULTS.

Oldfield [5] mentions that in his experience he has not encountered a case of adhesion of the placenta, and that the great error, especially with beginners, is that they fail to distinguish *between* retention of the placenta in the vagina and in the uterus. I think we may carry his line of thought further and say that very few of those cases in which the placenta remains in the uterus are cases of completely adherent placenta and that usually the retention is caused by some abnormality in the uterine musculature, either the formation of a contraction ring or atony of the muscle.

On looking through the reports of the Leeds Maternity Hospital during the last few years, I find that most of the operations for manual removal were performed by the house surgeon, whose average stay is about six months. In well over half the cases the notes show that "removal was difficult, ie placenta seemed to be firmly adherent," and gain, the report on the removed placenta showed iat it was ragged and questionably complete. his year thirteen consecutive cases treated by mbilical vein injection have all come to a successful sue except the first; and this was one in which ianual removal was being undertaken for a third me, and what is more important, this was the first ise treated by vein injection before we had really lt our way. Without in any way wishing to isparage the reports of any of my predecessors, cannot but think that the great bulk of placenta escribed as being adherent were either only partially dherent or merely retained.

I mention this point with a definite purpose· do not see how injection of the umbilical vein an possibly aid the separation of a placenta accreta, r the truly morbidly adherent placenta; but because his condition is extremely rare, the possibility of its resence should in no way discourage the accoucheur rom proceeding with injection of the umbilical vein. n all our cases the injection seemed to elicit uterine ontractions to a varying degree—in one case owerful enough to cause complete expulsion of he placenta before the injection of the saline was inished. The cause is undoubtedly due to the udden increase in the bulk of the uterine contents nd can be likened to the procedure of passing the and inside the uterus in an attempt to stop post-artum hæmorrhage. This also agrees with our indings, that the quicker the injection of the fluid s made the sooner do the uterine contractions ppear.

Five of the cases described above had abnormal lacentæ. These were white and fibrous, with nultiple white nodules, presumably formed from ld hæmorrhages, with complete absence of cotyledons. The question that naturally arose was, were these placentæ in anyway morbidly adherent, and if so, by what mechanism were they detached?

During the investigation of the injection of the recently delivered placentæ it was noticed that as the injection proceeded, the placenta became firmer and firmer, that the folds became undone and the spaces between the cotyledons filled up so that when the injection was complete the placenta had lost its soft consistency and now resembled a rubber disc, being solid enough to stand upon its edge when held in the hand. We consider that when the placenta is injected in utero the events are similar and that the placenta formerly lying in folds in the uterine cavity straightens out, its solidity increasing, while portions loosely adherent are torn away from the uterine wall. At the same time the onset or increase in strength of uterine contractions expels the placenta into the lower uterine segment or vaginal vault. A similar explanation suffices for those placentæ held by a contraction ring.

In contrast to the views of other writers, the cases mentioned above seem to show the extreme value of the Mojon-Gabaston manipulation in post-partum hæmorrhage. In twelve out of the thirteen described, bleeding was the main indication for obtaining delivery of the placenta. This is the only condition which calls for urgent treatment, and I hope I have shown that an adequate and easy method is available, involving the slightest amount of manipulation, very little in the way of surgical instruments, and no preparation, such as anæsthesia or special surgical technique, on the part of the accoucheur. The results, so far as a series of thirteen cases can show, were nearly all completely successful. Throughout the whole series there was not one case of uterine infection, and in none did the injection seem to cause any suggestion of shock, as estimated by the general condition, the pulse, and the blood pressure of the patient.

The rapidity of the manipulation is obvious, in nearly all the cases from the onset of the injection to the final delivery of the placenta not more than five minutes elapsed, a short space of time compared with that taken in the preparation for and completion of the delivery by manual removal. This is a factor to be considered when dealing with a patient who is continuously oozing blood. Other points which are noticeable are:—

(1) The value of the method in cases of ante-partum hæmorrhage after delivery either accidental or unavoidable, where the patient's general condition is such that a further loss would be detrimental. One need not await the physiological separation of the placenta, but by artificial means complete the third stage at once.*

(2) The placenta may be obtained before attempts are made to suture injuries to the genital tract, and thus overcoming the presence of the cord and the continuous loss of blood which obscure the field of operation.

(3) In cases of premature labour with retained placenta, the injection of the vein causes an increase in size of the uterus, enabling the accoucheur to obtain a firmer grasp of the uterus and effect a Credé manœuvre when this is necessary.

In conclusion, I wish to point out that the method presents to the doctor, whether of a clinic or in general practice, an easy means of obtaining completion of the third stage of labour, without the aid of any further instruments than he normally carries in his bag; without the necessity of much preparation or anæsthetic, with a fair percentage proportion of success, and above all without the great fear of puerperal infection and risk of death which accompanies the manipulation now generally practised—namely, "manual removal."

SERUM AGGLUTINATIONS TO THE TYPHOID GROUP

IN CASES OF PULMONARY TUBERCULOSIS.

By J. R. A. Madgwick, M.B. Lond., D.P.M.,
ASSISTANT MEDICAL OFFICER, LONG GROVE MENTAL HOSPITAL;
AND
F. Partner,
ASSISTANT IN THE CENTRAL PATHOLOGICAL LABORATORY
OF THE LONDON COUNTY MENTAL HOSPITALS.

In the course of a number of typhoid agglutination tests for diagnostic purposes it was observed that anomalous reactions might occur in cases of pulmonary tuberculosis. These anomalous reactions have been noted by other observers, who have criticised the specificity of the agglutination tests on this account. Krencker[1] examined 26 cases of tuberculosis and found that 16 of them gave positive agglutination tests to the typhoid group (61·5 per cent.). Reactions were obtained in varying dilutions up to 1/500, and in a number of cases which were repeated the agglutinins persisted.[2] [3]

---

* Mr. Oldfield has called our attention to cases where the placenta is delivered immediately after the birth of the child, associated with only the slightest loss of blood.

The occurrence of a large number of patients suffering from pulmonary tuberculosis in the London County Mental Hospitals made it possible to investigate by modern methods the nature and extent of these anomalous reactions, and in this communication the agglutination reactions to the typhoid group of a series of tuberculous cases have been tested using Dreyer's technique and the Oxford standard agglutinable cultures. All the cases were suffering from undisputed pulmonary tuberculosis, and it was ascertained that no case had been inoculated with T.A.B. vaccine, neither was there any history of typhoid or paratyphoid fever infection.

The number of cases examined was 73, and of these 25, or 34·2 per cent., showed agglutinins to either one, two, or all of the typhoid group of organisms. The total incidence of positive agglutination reactions is shown in Table I., and the simultaneous occurrence of the respective agglutinins is shown in Table II.

TABLE II.

Typhoid, Para. A and Para. B	7	Paras. A and B	1
Typhoid and Para. A ..	2	Typhoid only	5
Typhoid and Para. B ..	6	Para. A only	Nil.
		Para. B only	4

The strength of the reactions, recorded in terms of standard agglutinin units per cubic centimetre of serum, was as follows:—

B. typhosus— Showed an average of 17·7 units.	Highest recorded ..	40·0
	Lowest " ..	3·5
B. paratyphosus A— Showed an average of 17·1 units.	Highest " ..	48·0
	Lowest " ..	5·0
B. paratyphosus B— Showed an average of 26·2 units.	Highest " ..	60·0
	Lowest " ..	5·0

In nine cases the examinations were repeated after three months and in each case the reaction persisted with but little variation in titre. The full results on these cases are given in Table III. and exemplify the average titre obtained in these anomalous reactions and the persistence of the reaction.

TABLE III.

Case No.	1st examination.			2nd examination.		
	T.	A.	B.	T.	A.	B.
1	Neg.	Neg.	+30	Neg.	Neg.	+11·9
2	+10	+15	+30	+ 7·9	+13·6	+59·5
3	Neg.	+ 6 5	Neg.	Neg.	+ 6·5	Neg.
4	+40	Neg.	Neg.	+39·6	Neg.	+11·9
5	+15	Neg.	Neg.	+ 7·9	Neg.	Neg.
6	+ 8	+15	+ 6	+ 3·9	+13·6	Neg.
7	+20	Neg.	Neg.	+19·8	Neg.	Neg.
8	+ 8	Neg.	+60	+ 7·9	Neg.	+59·5
9	+30	+15	+10	+39·6	+13·6	+11·9

The greatest alteration in strength of titre was in case No. 2, positive to *paratyphosus* B, which increased from 30 to 59·5 standard agglutinin units per cubic centimetre. In cases Nos. 3, 7, and 8 no appreciable change occurred.

CONTROLS.

It might be suggested that a similar incidence of positive reactions could occur in any series of cases taken from a mental hospital population, especially in view of the work of Gilfillan and Mann,[4] and McCowan and Mann,[5] who showed the existence of definite typhoid carriers amongst mental hospital inhabitants who gave no previous history of typhoid infection.

In order to control the preceding observations on tuberculous cases the agglutination reactions to the typhoid group of organisms of 100 cases of some years' residence in mental hospital, but showing no evidence of tubercle, were investigated. Of the 100 cases examined 95 gave completely negative reactions to *B. typhosus*, *B. paratyphosus* A, and *B. paratyphosus* B, and the remaining five gave slightly positive results; details of these cases are given below (Table IV.).

TABLE IV.

Case No.	Agglutination reactions.			History of case.
	B. typh.	*B. para.* A.	*B. para.* B.	
1	+3	Neg.	Neg.	Had lived in Canada for some years prior to being admitted to Long Grove Mental Hospital. No history of T.A.B. inoculation or infection.
31	+3	Neg.	Neg.	Had lived in America for three years. No history of T.A.B. inoculation or infection.
57	Neg.	Neg.	+6·25	No history obtainable.
58	+6·25	Neg.	+12·5	Had served abroad in the Army.
62	+6·25	Neg.	Neg.	Deaf-mute. No history obtainable of T.A.B. inoculation or infection.

SUMMARY.

Seventy-three cases of pulmonary tuberculosis with a negative history of T.A.B. inoculation or infection have been examined for agglutinins to the typhoid group of organisms and these were found to be present in the blood of 25, or 34·2 per cent.

These 25 cases showed reactions of diagnostic significance, which persisted for three months during the course of the investigation.

Control investigations of 100 cases of non-tuberculous mental hospital patients showed slightly positive reactions in five cases only, one of which was possibly the result of prophylactic inoculation against the typhoid group of fevers during army service.

The results suggest that in a case showing persistent agglutination reactions of average low titre and not showing the rise of titre associated with the progress of true typhoid infections, the possibility of tubercle should not be overlooked.

In conclusion, we would thank Dr. D. Ogilvie for permission to publish these records, and Dr. F. L. Golla, Director of the Laboratory, and Mr. S. A. Mann, D.Sc., for their encouragement and advice in the course of this investigation.

CLINICAL AND LABORATORY NOTES

TWO CASES OF AUMATIC DISLOCATION OF THE HIP IN CHILDREN.

BY PHILIP GLYNN, M.R.C.S. ENG.,
LATE HOUSE SURGEON TO THE BELGRAVE HOSPITAL FOR CHILDREN.

THESE two cases of traumatic dislocation of the hip children were seen at one hospital within a year. adults it is an uncommon injury forming only per cent. of all dislocations, while in children the idence is considerably less. C. C. Choyce,[1] up to 24, was able to collect only 59 recorded cases. e reasons for its relative rarity probably are the bility of the joint, the strength of the surrounding aments and muscles, and the depth of the acetulum, while in children the injury that would duce dislocation in an adult is more likely to ing about separation of the epiphysis of the head the femur.

The dislocation is usually due either to a weight ling on the back while the subject is in some sort squatting position, or to a fall and landing with e leg bent under the body. The former is the ual cause of dislocation of the hip in miners, among hom the injury is probably much commoner than the rest of the population. Whatever the cause, e course of events is the same, the Y-shaped iliomoral ligament acting as a fulcrum, the head of e femur is forced through the weak portion of e capsule between the pubo-femoral and ischiomoral ligaments, its ultimate position in relation the acetabulum, either anterior or posterior, pending on whether the limb was abducted or adducted at the time of the injury; if the former, an anterior, and if the latter, a posterior dislocation is produced.

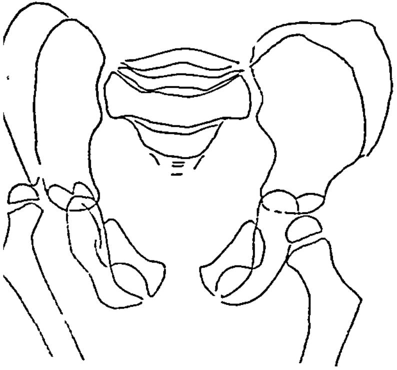

FIG. 1 (Case 1).

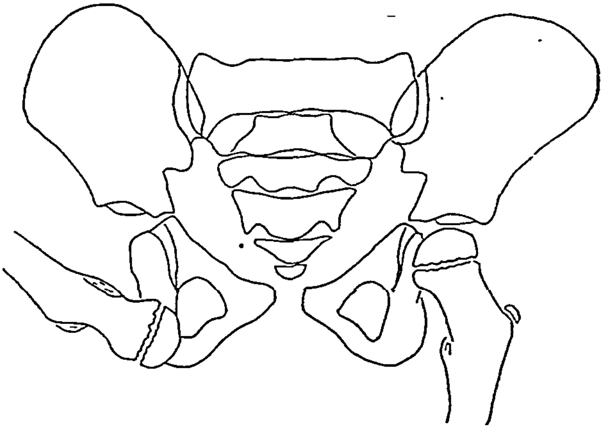
CASE 1.—A child, aged 3 years 11 months, was admitted to the Belgrave Hospital with a history of having fallen ut of bed with the right leg "twisted" under him. The ccident had occurred five days previously. The right g was adducted, flexed and internally rotated, and the ead of the femur could be felt in the gluteal region. X rays howed a sciatic type of dislocation, the head of the femur ring in the great sacro-sciatic notch (Fig. 1). A general næsthetic was given and reduction effected by Bigelow's ircumduction method.

This case illustrates the trivial accident which may roduce a dislocation when the muscles are relaxed, he child probably having been asleep when he fell ut of bed.

CASE 2.—A girl, aged 7 years, had been sliding down the anisters and had fallen about 10 feet into the hall below; her legs were said to be doubled beneath her. The child, seen within 15 minutes of the accident, was in extreme pain, the right thigh was almost fully flexed at the hip, abducted more than is normally possible, and externally rotated. The head of the femur could be felt above and anterior to the tuber ischii. A skiagram showed the head of the femur to be resting against the posterior lip of the acetabular notch (Fig. 2). Anæsthesia was induced with open ether and reduction was very easily effected. An adventitious movement slightly extending the thigh, the head slipped back into place before any attempt at reduction had been made.

FIG. 2 (Case 2).



This case is of interest because the head of the femur had been arrested in the first stage of dislocation and had not taken up either an anterior or posterior position. It is noteworthy that the child was supporting her right knee as though fearful that something worse might happen if she let it go. The case bears a striking resemblance to the subglenoid or luxatio erector type of dislocation occurring at the shoulder-joint.

The second case, seen 11 months after the accident, showed no disability as the result of the dislocation, and a skiagram of the hip was normal. The first case unfortunately cannot be traced.

I am indebted to Mr. C. P. G. Wakeley and Mr. R. A. Ramsay for permission to publish these two cases.

RUPTURE OF THE URETHRA.

BY A. C. FISHER, M.B. BRISTOL, F.R.C.S. ENG.,
OF THE KALENE HILL HOSPITAL, N. RHODESIA.

ON August 21st, 1931, a man, aged 40, presented himself for treatment. He gave a history of old-standing gonorrhœa. Four years ago, following a period of difficulty of micturition, he became entirely unable to pass water. This retention was followed by abscess formation and a severe illness.

On examination the man, who had walked 80 miles for treatment, was emaciated. The penis, scrotum, and pubes were swollen, but while the suprapubic tissues and penis pitted on pressure, the skin of the scrotum and perineal region was as hard as crocodile hide. On micturition, urine discharged itself through about a dozen sinuses above the pubes, in the peno-scrotal angle, and through a perineum which was riddled with sinuses. A few drops passed the meatus, which was contracted to a pinhole. Fortunately the stricture did not prove impassable, and with its dilatation and a plastic enlargement of the meatus, micturition became normal, and all the sinuses closed and healed rapidly.

This case had obviously been one of rupture of the urethra, and the survival of the patient for four years after such a catastrophe without treatment was only less remarkable than his dramatic recovery following the simplest of procedures.

ATYPICAL HODGKIN'S DISEASE.

By Major Amir Chand, M.B. Punjab,
F.R.C.P. Edin., I.M.S.,
PRINCIPAL AND PROFESSOR OF MEDICINE, MEDICAL SCHOOL, AMRITSAR, INDIA.

Atypical Hodgkin's disease with a leukæmic blood picture is rare. Leucocytosis, sometimes fairly high, may be met with in Hodgkin's disease, but I am not aware of any record of it with a total leucocyte count of well over 100,000, and a large number of myelocytes and metamyelocytes.

A man, aged 40, was admitted on Dec. 7th, 1931, complaining of swelling of both sides of the neck, axillæ, and groins (duration eight months), and swelling of the legs, abdomen, and face (duration seven months). He dates his illness from an attack of shivering (? fever) about a year ago. Since then weakness, disinclination for work, lethargy, and lassitude have been steadily increasing. A little work would make him feel breathless and exhausted. About a month later he felt pain round about the left iliac crest. This was followed by pain in the abdomen with flatulent distension. Some three weeks afterwards he noticed small swellings on both sides of the neck, then in the inguinal regions, and a little later in the femoral regions. Within a short time of the latter, œdema appeared on the feet, at first on the left and then the right, and it has steadily extended up the legs, scrotum, trunk, and face. About a month after the appearance of œdema, swellings appeared more or less simultaneously in both the axillæ.

He has now marked œdema almost all over the body, only the hands, the upper part of the chest, and the scalp being free from it. He looks very anæmic. Spleen is two fingers below the costal margin, its edge sharp, surface smooth; it is fairly hard in consistence, and is not tender or painful. The liver is one finger-breadth below the costal margin; its margin is sharp, and surface smooth and fairly hard, free from pain or tenderness. Almost all the superficial glands are enlarged, they vary in size from a pea to a hen's egg; a few are soft, others are hard, most of them are free, but some are adherent to each other, producing large masses, some about the size of an orange; none is adherent to the deeper structures or to the skin; the enlargement is almost symmetrical, altogether painless, and free from tenderness on pressure. There are signs of enlargement of the deeper glands, and from the history it appears as if they were the first to be affected

During the period of a little over two months that he has been under observation there has been a slight rise of temperature (maximum 100° F.) on five occasions, but unaccompanied by any feeling of feverishness. Previous to that there may have been similar rises, but the temperature was never taken as he did not feel feverish.

Blood count has been done repeatedly and independently by different workers (hence the different terminology used), but it will do to quote a few of the results.

Dec. 9th: total red cells, 2,630,000 per c.mm.; hæmoglobin, 56 per cent. (Sahli); total white cells, 128,000 per c.mm.; polymorphs, 53 per cent.; myelocytes, 22 per cent.; metamyelocytes, 22 per cent.; lymphocytes, 3 per cent.

Dec. 21st: total red cells, 2,700,000 per c.mm.; polymorphs, 54·5 per cent.; myelocytes, 38·2 per cent.; lymphocytes, 5 per cent.; large mononuclears, 2 per cent.

Jan. 1st, 1932: total leucocytes, 22,500 per c.mm.; polymorphs, 53·3 per cent.; myelocytes, 43·3 per cent.; lymphocytes, 3·4 per cent.

Feb. 17th: total red cells, 2,590,000 per c.mm.; hæmoglobin, 60 per cent. (Sahli); total white cells, 28,200 per c.mm.; polymorphs, 70 per cent.; metamyelocytes, 4 per cent.; myelocytes, 7 per cent.; lymphocytes, 18 per cent.; eosinophiles, 1 per cent.

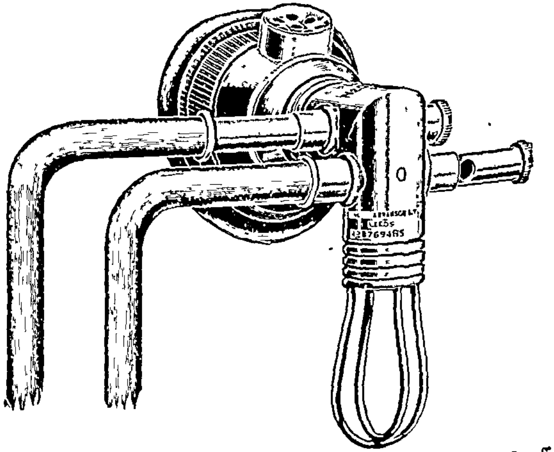
Thus the blood picture, which first resembled that of myeloid leukæmia, showed a marked change after a few weeks, in that the total leucocyte count came down by about a hundred thousand, and the number of polymorphs went up at the cost of myelocytes and metamyelocytes.

A gland was removed from an axilla and examined independently by two pathologists. Their reports are: (1) "Section of the gland shows proliferation of endothelial cells. No eosinophiles were seen. I think it is an atypical case of Hodgkin's disease, with a leukæmic blood picture and endothelioma-like glandular changes." (2) "Sections show sheets and masses of large round cells with faintly staining but clear protoplasm, and moderately chromatic vesicular nuclei. These cells definitely exhibit vasoformative character, and are therefore endothelial in origin. When examined with 1/12th oil-immersion lens some cells show multilobed nuclei. On the whole, stroma is scanty, but in some places there is definite evidence of fibrous tissue development, particularly around the large blood-vessels. At the margins of the sections in some places one finds remains of the lymph gland structure. Atypical Hodgkin's disease."

NEW INVENTIONS

A SIMPLIFIED ANÆSTHETIC APPARATUS.

The apparatus here illustrated introduces a method of administering gas and oxygen in midwifery suitable for the general practitioner. A gas and an oxygen cylinder is fitted with Pinson valves, and connected each by a separate rubber tube with a Clover's ether apparatus, the bag mount of which is fitted with two slot valves, one for each rubber tube. The slot valves which are fitted to the angle piece holding the bag enable either gas, oxygen, or both, to be given in any quantity, and ether can be turned on and off at will. This simple and portable apparatus enables gas and oxygen to be given alone, with the face piece if desired. If deeper anæsthesia is required for operative work or the application of instruments, the ether chamber may be added. There has been an absence of shock and hæmorrhage in all cases where the apparatus has been employed, while the use of such small quantities of ether makes for safety in bedrooms with open fires and gas jets.



The slot valve is made by Messrs. Reynolds and Branson, Ltd., Leeds.

G. R. Potter, M.R.C.S.

MEDICAL SOCIETIES

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

THE annual congress of this society took place at he University, Edinburgh, from May 12th to 14th, he new President, Dr. A. H. H. SINCLAIR, occupying he chair. In his opening address he made a further ontribution on the intracapsular extraction of ataract, with a motion picture showing the operation s he carried it out. In the Bowman Lecture Prof. Dr. J. VAN DER HOEVE dealt with Ocular Movements.

A paper was contributed jointly by Mr. SPENCE MEIGHAN and Mr. NORMAN M. DOTT on

Intracranial Resection of the Optic Nerve in Glioma Retinæ.

They recalled the work of A. B. Reese, of New York, who had shown that of eyes removed on account of glioma retinæ, 52 per cent. showed invasion of the optic nerve and that in 81 per cent. of these invaded nerves severance of the nerve at enucleation was distal to the disease extension. Hence 43 per cent. of all cases of enucleation for glioma were doomed to failure before the patient left the operating room. Yet this tumour showed little tendency to invade other than its parent nervous tissues. Death was due to backward extension to the optic chiasm and brain, not to local spread, or to glandular or blood stream metastasis. These were the facts which had led Mr. Meighan and Mr. Dott to do a more radical operation than the usual one in a patient—a girl of 2½. The child was brought because of the peculiar appearance of the left pupil and associated discomfort; a whitish appearance of the pupil had been noted six months previously. There was some congestion in the eyeball, the pupil was semi-dilated, and the anterior chamber was shallow. The intra-ocular tension was 40 mm., but there was neither proptosis nor glandular enlargement. The other eye was healthy. Glioma retinæ was diagnosed, and enucleation advised. At the operation there was difficulty in dislocating the globe; the optic nerve was severed with the globe still in the orbit. Eventually canthotomy had to be done to extract the detached eye. The sclera was intact. Histological examination revealed a characteristic retinoblastoma. The tumour had found its way along the neural tissue of the optic nerve through the lamina cribrosa, and along the interseptal pathways of the nerve. Seven days after the enucleation the orbit was reopened and an attempt made to secure a further portion of the remaining nerve at the apex of the orbit, but Mr. Dott could not satisfy himself that the nerve had been re-exposed. Fourteen days after enucleation a radium bomb was directed on to the orbit for two 48-hour periods. Then, as there was no apparent involvement of the optic nerve or chiasm opposite, he entered upon an intracranial resection of the optic nerve, and removed the entire length of that nerve to the optic chiasm. The operation was detailed, with the aid of drawings and slides. Some sepsis occurred, but subsided, and since the procedure the child's health had been excellent.

The whole of one morning was devoted to the discussion of the pre-operative and post-operative management and the complications of

Senile Cataract.

Dr. A. J. BALLANTYNE, in opening, dwelt chiefly on the complications likely to arise and how to guard against them, and on the preparation of the patient. The removal of a cataractous lens through the wall of the eyeball might sound a simple procedure, but it was surrounded with possibilities of disaster. All the standard operations could produce excellent results, but antisepsis and asepsis had not proved of the same value in ophthalmology as in general surgery, though wound infection now occurred less frequently than 30 years ago. Infection might not be obvious until as long as 72 hours after the operation. Apparently ocular inflammations were not always association with trauma; exogenous infection played a large part even in low-grade inflammations. With regard to prophylactic asepsis, many operators found that their dexterity was hampered by rubber gloves, but that both surgeon and assistants should wear masks covering mouth and nose during operation. The danger arising from chronic dacryocystitis could be avoided by excising the sac, ligaturing the canaliculi, or cauterising the puncta before considering the intra-ocular operation. It was his practice to have a culture made from the conjunctiva two days before operation, and to have the eye cleansed twice a day by irrigation with normal saline, followed by acriflavine drops (1 in 1000), with a final application of lotion and drops just before operation. If cocci were abundant in the area on the day appointed operation was postponed, and drops of 1 per cent. mercurochrome were added to the former routine.

Pre-operative measures included treatment of glycosuria, removal of septic teeth and other obvious foci of sepsis, and a purgative. Latent syphilis and tubercle could cause uveal inflammation after cataract extraction, and diabetics were more liable to hæmorrhage and to iritis than were normal persons. Should hyperglycæmia appear after operation, insulin should at once be given. Albuminuria in itself was not a bar to the operation, but it might indicate cardiovascular or renal disease. Glaucoma might follow this, as any other, type of operation, and the interval before it supervened might be as long as 20 years. Iridectomy and sclero-corneal trephining seemed to give the best results in the presence of glaucoma.

Sir ARNOLD LAWSON pointed out that the conjunctiva was, in the ordinary course, clean, and therefore he regarded most of the antiseptic washings and other precautions against contamination as needless, and indeed irritating. No cataract operation should be undertaken if in the particular case there was likelihood of pathogenic infection. All he considered necessary was to exclude the presence of conjunctival discharge, which was a sign that dangerous organisms were present. It was important that the patient should be in his best health at the time of operation, especially as most of the subjects of cataract were well advanced in years.

Mr. R. FOSTER MOORE gave as his deliberate opinion that no intracapsular extraction of cataract operation would stand the test of time, because of the outstanding danger of loss of vitreous. Moreover, the behaviour of the patient, which was beyond the surgeon's control, exerted a great influence on the result of such operations. Some regarded a loss of vitreous as of comparatively little moment, but he ranked it as the worst accident which could happen during the operation.

Blindness and its Certification.

Papers on this subject were read by Mr. JOHN MARSHALL (assisted by Mr. C. M. SMITH) and Dr. C. W. GRAHAM. Mr. Marshall said that during the past year the methods of examining and of certifying blind persons had been the subject of reports from the Department of Health for Scotland, the Council of British Ophthalmologists, and the Prevention of Blindness Committee of the Union of Counties Associations for the Blind. There were minor differences in the recommendations in these reports, and it was felt that the society could help to secure the adoption of a system which should operate uniformly over the whole kingdom. As regards definition, the committee of the Royal Society of Medicine had stated: "Experience shows that persons whose acuity is below one-twentieth *of the normal—i.e., 3/60 Snellen—are* usually unable to perform work requiring eyesight, while persons with vision better than one-tenth are usually able to perform some such work. Persons with intermediate degrees may or may not be able; much depends on the intelligence or bodily strength, and much on the nature of the blindness."

Mr. LESLIE PATON remarked that the definition of blindness which had been adopted at Geneva was one in which he felt a parental interest—namely, a blind person was one so blind as to be unable to perform work for which sight was usually essential.

Mr. J. H. FISHER expressed the admiration he felt, which was shared by his English colleagues, of the great lead which Scotland had given in this matter of *certification of the blind.* He agreed with those in Scotland that the right system was the clinic system. In scattered parts of the country where certain of the patients could not come under the observation of the clinic it was his strong view that the coöperation of two surgeons was the solution. There was difficulty, in regard to a specific standard, in determining whether a person should be put into the category of the blind or into that of the non-blind. He thought some latitude should be given to the certifying surgeon, or preferably surgeons. There were patients whose direct sight, especially distant vision, might be very low, who were able to read ordinary school-books. One could not deny that in some cases incapacity was exaggerated by the patient when it was a question of obtaining money. It was hoped to be able to establish a reliable census of blind persons, and a determination of the causes of blindness; this information, when obtained, would provide the best pointer to the best methods of prevention.

Mr. J. TUDOR THOMAS read a communication, illustrated by slides, on

Transplantation of Scleral Tissue on to Rabbit's Cornea.

He had carried out this transplantation on five rabbits, and in all of them the graft was well united. He found it more difficult to be precise with this operation than with transplantation of cornea. If the graft was to remain avascular, it was essential that union should be secured of all its parts. He had established the facts that (1) scleral tissue could be successfully transplanted to replace the whole thickness of the cornea; (2) the opacity in successful scleral grafts became less; (3) it was possible to graft scleral tissue on to the cornea without any vascularisation taking place, under the same conditions as those which resulted in transparent grafts of corneal tissue.

During the congress many clinical cases were inspected and discussed. A museum of ophthalmological exhibits had been organised by Miss Ida Mann.

MANCHESTER MEDICAL SOCIETY.

AT a meeting of this society on April 6th Dr. R. RALSTON PATERSON read a paper on the

Radio-sensitivity of Tumours.

Tissues, he said, vary markedly in their response to radiation. The property of tissue which underlies this variable response is called *radio-sensitivity,* or at the other end of the scale radio-resistance. In particular, tumours show a wide range of such sensitivity. By contrasting the sensitivity of growths with the sensitivity of the skin—in both cases using the minimum. lethal dose as the standard—it is possible to group tumours into four groups.

(1) *Radio-sensitive Group.*—This is pathologicall a heterogeneous group of growths, but clinicall the group includes many highly malignant growth which metastasise early. The lethal dose for thi group of tumours is less than the lethal dose fo the skin, and thus sufficient radiation to produc lethal changes can be given by external method alone. External methods of irradiation. X ray in larger tumours, external radium in mor localised tumours, thus become the treatment choice.

(2) *Epitheliomata.*—In this group are included als the epithelial tumours of breast, excepting tru adenocarcinoma, because whatever their natu *they act from the point of view of their reaction* radiation as do the squamous epitheliomata. Th group includes a high proportion of the malignan tumours and is therefore correspondingly importan To produce lethal changes in those growths, a quanti of irradiation must be used which is approximate in the region of the lethal dose for skin. Th therefore do not lend themselves to satisfacto curative treatment by external methods of irradiati alone. In practice they have to be treated, treated by irradiation at all, by "localised" irra ation, which can only be achieved by means radium. The treatment of choice must therefore between such localised irradiation methods a surgery. This choice is made by a contrast of t ease or difficulty of technical procedures involve of functional results, or of probable survival by one other method.

(3) *Adenocarcinomata.*—In this group growths appe to require a lethal dose greater than the skin leth dose, and normally equal to the lethal dose the tumour bed. Irradiation, whether external localised, therefore can only act as a cautery. view of the fact that there are many safer a less expensive cauteries, irradiation seems contr indicated, and the treatment of choice in this gro is always surgery.

(4) *Radio-resistant.*—This group consists of a gro of tumours heterogeneous pathologically, but the most part of connective tissue origin. Li normal connective tissue they are highly radi resistant, and it would appear that the lethal do for these tumours is not only greater than the leth dose for skin, but even greater than the lethal do for the normal tissues in which these tumours te to grow. The use of irradiation to effect dire curative action therefore appears more likely to damage to the normal than to the abnormal tissu and is *therefore definitely* contra-indicated. this group, however, should surgical extirpation impossible, another process becomes valuable, th

alled by Ewing "growth restraint." Here, repeated nall doses of irradiation are used to produce an ffect on the endothelial lining of the vascular system f the tumours. A process resembling endarteritis bliterans ensues, with resulting cessation of, or arked slowing of growth.

These four groups thus cover the whole field of umours, and give us an indication as to the choice of reatment once we know in which group any particular umour belongs. In this chapter of radio-sensitivity here are two likely fields for research work in the uture. In the pathological field there is the problem f ascertaining the exact criteria underlying the elationship between pathological types and radio-ensitivity. In the experimental field attempts are eing made to increase radio-sensitivity, either by lterations in the time-factor of treatment, or by ntravenous methods. Could such increased radio-ensitivity be produced, tumours would then be rendered more amenable to irradiation methods.

Prof. S. L. BAKER read a paper on the

Virus Theory of Cancer.

Although many and various predisposing "causes" of cancer are known, he said, the fundamental cause of the abnormal cell proliferation, which is the central fact of cancer, can be narrowed down to two possibilities:—

(1) The *biological* or *mutation theory*, which postulates an alteration or mutation of the cell initiated by some chemical or physical stimulus. This change once initiated is handed on to subsequent generations of cells by the ordinary laws of cell inheritance—the persistence of an acquired character.

(2) The *virus theory* postulates a continuously acting cause; an infection of the cell by an agent which multiplies and is thus carried on through successive generations of cells.

In the case of mammalian tumours there is a great weight of both histological and experimental evidence in support of the cell as the "cancer unit." Cancer in mammals can be transmitted experimentally only by grafting living tumour cells to new hosts of the same species. No cancer-causing agent has ever been separated from the cells of mammalian tumours. There was no experimental evidence that suggested that a living virus could be responsible for the production of a tumour until, in 1911, Peyton Rous published his first account of a fowl sarcoma transmissible experimentally from bird to bird by a filtrable agent separable from the tumour cells. It is now known that many different types of sarcoma in the fowl can be transmitted in this manner. The fowl sarcomata, apart from this peculiar property of filtrability, differ in no way from mammalian sarcomata. The tumours occur sporadically and there is no evidence of infectivity under natural conditions. The tumour is essentially a local lesion and there is considerable evidence to show that metastases are produced by detached cell fragments, as with mammalian tumours, and not by the dissemination of the infective agent about the body. A strain of fowl sarcoma is not always filtrable and often passes through stages where it can only be transmitted by cell suspensions. Carcinomas occur in fowls but a transplantable strain has never been established, and their filtrability has therefore not been studied.

The exact bearing of these fowl tumours upon mammalian cancer remains at the present time a matter of conjecture, but the facts so far obtained are so peculiar and striking that a continued investigation of them is clearly indicated.

REVIEWS AND NOTICES OF BOOKS

Antigens in the Light of Recent Investigations.

By OLUF THOMSEN, Professor of General Pathology at the University of Copenhagen. Translated from the Danish by HANS ANDERSON, M.D. Copenhagen: Levin and Munksgaard. 1931. Pp. 187.

THIS valuable monograph is a review of the modern position of the antigenic structure of proteins and bacteria. The former are considered with especial reference to their antigenic constitution, the chemical modification of antigenic specificity, and the question of haptenes. Haptenes, as is to be expected, are largely dealt with from the point of view of group and type characters, and the influence of soluble carbohydrate haptenes in determining types. This naturally involves an especially detailed consideration of the pneumococci, although Lancefield's work upon the hæmolytic streptococci and Julianelle's investigation of the Friedländer group are given adequate treatment. The complex question of the constitution of toxins, the basis of the Wassermann test, and allergy are also discussed. It is hardly to be wondered at that Prof. Thomsen is less successful in dealing with these problems than with the more straightforward ones of antigenic structure. The book contains full references and the author has shown good judgment in the selection of his data from the large mass of material at his disposal. The English translation is excellent.

Wheeler and Jack's Handbook of Medicine.

Ninth edition. Revised by JOHN HENDERSON, M.D., F.R.F.P.S. Glasg., Physician, Glasgow Royal Infirmary; Professor of Medicine, St. Mungo's College, Glasgow. Edinburgh: E. and S. Livingstone. 1932. Pp. 654. 12*s.* 6*d.*

"Wheeler and Jack" is as valuable now to the student and practitioner as it has ever been in its 40 years of existence. Like all standard text-books, it has an impersonal quality; it is greater than any of its authors. Dr. Alexander Wheeler laid its foundations in the first seven years, and Dr. W. R. Jack built up from his tradition a work which, while appearing the same, has evolved with the momentous development of medicine in our times. Dr. Jack died in 1927, but his successor, Prof. John Henderson, proves himself in the ninth edition to be a worthy successor. He has thoroughly revised the book and made many modifications and additions, recasting the work on vitamins, gastric disorders, pernicious anæmia, arthritis deformans, and encephalitis lethargica. He has added sections on coronary thrombosis, bundle-branch block, syphilis of the stomach, hepatic efficiency, and cholecystography, acute febrile polyneuritis and narcolepsy, and various types of neurosis. Possibly the neurological and psychological sections of the book will increase in importance as the significance of these subjects is increasingly realised by examiners. It seems anomalous that a text-book should still contain many pages

Blindness and its Certification.

Papers on this subject were read by Mr. JOHN MARSHALL (*assisted by* Mr. C. M. SMITH) and Dr. C. W. GRAHAM. Mr. Marshall said that during the past year the methods of examining and of certifying blind persons had been the subject of reports from the Department of Health for Scotland, the Council of British Ophthalmologists, and the Prevention of Blindness Committee of the Union of Counties Associations for the Blind. There were minor differences in the recommendations in these reports, and it was felt that the society could help to secure the adoption of a system which should operate uniformly over the whole kingdom. As regards definition, the committee of the Royal Society of Medicine had stated: "Experience shows that persons whose acuity is below one-twentieth of the normal—i.e., 3/60 Snellen—are usually unable to perform work requiring eyesight, while persons with vision better than one-tenth are usually able to perform some such work. Persons with intermediate degrees may or may not be able; much depends on the intelligence or bodily strength, and much on the nature of the blindness."

Mr. LESLIE PATON remarked that the definition of blindness which had been adopted at Geneva was one in which he felt a parental interest—namely, a blind person was one so blind as to be unable to perform work for which sight was usually essential.

Mr. J. H. FISHER expressed the admiration he felt, which was shared by his English colleagues, of the great lead which Scotland had given in this matter of certification of the blind. He agreed with those in Scotland that the right system was the clinic system. In scattered parts of the country where certain of the patients could not come under the observation of the clinic it was his strong view that the coöperation of two surgeons was the solution. There was difficulty, in regard to a specific standard, in determining whether a person should be put into the category of the blind or into that of the non-blind. He thought some latitude should be given to the certifying surgeon, or preferably surgeons. There were patients whose direct sight, especially distant vision, might be very low, who were able to read ordinary school-books. One could not deny that in some cases incapacity was exaggerated by the patient when it was a question of obtaining money. It was hoped to be able to establish a reliable census of blind persons, and a determination of the causes of blindness; this information, when obtained, would provide the best pointer to the best methods of prevention.

Mr. J. TUDOR THOMAS read a communication, illustrated by slides, on

Transplantation of Scleral Tissue on to Rabbit's Cornea.

He had carried out this transplantation on five rabbits, and in all of them the graft was well united. He found it more difficult to be precise with this operation than with transplantation of cornea. If the graft was to remain avascular, it was essential that union should be secured of all its parts. He had established the facts that (1) scleral tissue could be successfully transplanted to replace the whole thickness of the cornea; (2) the opacity in successful scleral grafts became less; (3) it was possible to graft scleral tissue on to the cornea without any vascularisation taking place, under the same conditions as those which resulted in transparent grafts of corneal tissue.

During the congress many clinical cases were inspected and discussed. A museum of ophthalmological exhibits had been organised by Miss Ida Mann.

MANCHESTER MEDICAL SOCIETY.

AT a meeting of this society on April 6th Dr. R. RALSTON PATERSON read a paper on the

Radio-sensitivity of Tumours.

Tissues, he said, vary markedly in their response to radiation. The property of tissue which underlies this variable response is called radio-sensitivity, or at the other end of the scale radio-resistance. In particular, tumours show a wide range of such sensitivity. By contrasting the sensitivity of growths with the sensitivity of the skin—in both cases using the minimum. lethal dose as the standard—it is possible to group tumours into four groups.

(1) *Radio-sensitive Group.*—This is pathologically a heterogeneous group of growths, but clinically the group includes many highly malignant growths which metastasise early. The lethal dose for this group of tumours is less than the lethal dose for the skin, and thus sufficient radiation to produce lethal changes can be given by external methods alone. External methods of irradiation, X rays in larger tumours, external radium in more localised tumours, thus become the treatment of choice.

(2) *Epitheliomata.*—In this group are included also the epithelial tumours of breast, excepting true adenocarcinoma, because whatever their nature they act from the point of view of their reaction to radiation as do the squamous epitheliomata. This group includes a high proportion of the malignant tumours and is therefore correspondingly important. To produce lethal changes in these growths, a quantity of irradiation must be used which is approximately in the region of the lethal dose for skin. They therefore do not lend themselves to satisfactory curative treatment by external methods of irradiation alone. In practice they have to be treated, if treated by irradiation at all, by "localised" irradiation, which can only be achieved by means of radium. The treatment of choice must therefore lie between such localised irradiation methods and surgery. This choice is made by a contrast of the ease or difficulty of technical procedures involved, of functional results, or of probable survival by one or other method.

(3) *Adenocarcinomata.*—In

to require a lethal dose gre

dose, and normally equal to the lethal dose for the tumour bed. Irradiation, whether external or localised, therefore can only act as a cautery. In view of the fact that there are many safer and less expensive cauteries, irradiation seems contra-indicated, and the treatment of choice in this group is always surgery.

(4) *Radio-resistant.*—This group consists of a group of tumours heterogeneous pathologically, but for the most part of connective tissue origin. Like normal connective tissue they are highly radio-resistant, and it would appear that the lethal dose for these tumours is not only greater than the lethal dose for skin, but even greater than the lethal dose for the normal tissues in which these tumours tend to grow. The use of irradiation to effect direct curative action therefore appears more likely to do damage to the normal than to the abnormal tissue, and is therefore definitely contra-indicated. In this group, however, should surgical extirpation be impossible, another process becomes valuable, that

ebrantia, containing alcohol, chloroform, ether, nd the rest; the fourth, hypnotica, with chloral, ronal, sulphonal; and the last, excitantia, or mental imulants, which include tea, coffee, cocoa, tobacco, nd betel. All these are discussed in a manner which ill appeal to the general reader. The author's pinions on certain questions, such as the action of lcohol or the habit-forming properties of codeine, ay not commend themselves to orthodox pharmaco- ogists; prohibitionists may resent his gloomy rognosis of their efforts to save mankind from them- elves. But none can fail to be interested in this ucid and forceful account of narcomania, and in the uthor's views of the fundamental basis of drug ddiction.

Fraud in Medico-legal Practice.

By Sir JOHN COLLIE, C.M.G., M.D., Lt.-Col., R.A.M.C. London: Edward Arnold and Co. 1932. Pp. 276. 10*s.* 6*d.*

IN his new book on fraud in medico-legal practice Sir John Collie gathers together a mass of information and experience on the testing and detection of unsubstantial claims. Not only does he explain in detail how to deal with the wilful simulation of all kinds of symptoms and the deliberate exaggeration of an existing illness or injury; he also considers those borderline cases where hysteria is on the edge of fraud or where patients cannot summon up the will to go back to work. Converse examples of courage and resolution are common enough but doctors may not find it hard to recognise his picture of the patient who becomes obsessed with his illness, who merely marks time until legal proceedings are finished and damages or compensation are finally awarded, and who, after repeated medical examinations and the prolonged receipt of sick allowances, begins to feel a sense of having been wronged. When actual physical injury has subsided, subjective symptoms appear. Traumatic neurasthenia may be far more serious than the initial accident and its immediate consequences. Cases which were at first not fraudulent may end in fraud through want of pluck, "their idleness, their introspection, the attitude of their medical attendants, all combine to demoralise them." Whole-hearted fraud employs endless cunning. The successful counter-methods and ruses recounted by Sir John Collie show how ingenuity can meet its match.

Naturally the effect of the book suggests a sceptical outlook upon claims for damages or compensation. As the preface observes, deserving cases may receive less than their due share of consideration if unworthy persons make improper calls upon help and sympathy. Insurance against industrial accidents and sickness costs far more than the original actuarial estimates. The last report on the Workmen's Compensation Acts contained an official estimate that their total cost to all the industries and employments of the country is over twelve million pounds a year. Here, therefore, as in other social services, any lowering of the standard of care in examining claims or certifying disabilities means an immense wastage of money and indirectly a vastly increased burden upon the community. The medical witness will be asked to give his opinion, either in the law courts or in the preliminary stages of considering a claim. The book contains an admirable chapter on the law of libel, which explains the extent of privilege as well as giving some useful hints on preparation for the witness-box.

Life of Mendel.

By HUGO ILTIS. Translated by EDEN and CEDAR PAUL. London: George Allen and Unwin, Ltd. 1932. Pp. 336. 12*s.* 6*d.*

THIS book is written by the right author, for Dr. Iltis is the present Principal of the Deutsche Volkshochschule in Brünn, was secretary to the International Mendel Memorial Committee some 20 years ago, and is himself known as a specialist in botany through his great volume on the world's flora. But in spite of this aptitude for the subject, Dr. Iltis confesses that he has found considerable difficulty in obtaining material for the biography; Mendel kept no diary; and as a priest he had neither correspondence with women—and letters to women often form the most revealing part of a career—nor freedom in the utterance of philosophical views. By personal taste, however, he was a reserved man—so reserved that at his death it occurred to no one in his own monastery that he was a man of great mark. They knew him as an energetic prelate, who faced lay authority in defence of their rights, and as a hard-working public servant in several departments of agriculture and political economy; but his science they regarded as his amusement (which it was) and as no more. The few documents which he left behind him were burnt. Thus it came about that his short monograph on heredity was forgotten for decades, to be rediscovered in 1900, and give its remarkable impetus to the doctrines of the subject.

This short life is well written. In the first chapters we get detailed indications of the kind of man Mendel really was, and of the manner in which he acquired knowledge and reacted to his environments. We see that his temperament was practical and averse from premature or unsupported speculation, and that his range of experiment was much larger than is usually supposed. Much of his biological work was never mentioned by himself, as he knew that it would give offence to clerical zealots that he should be so employed. His botanical experiments were begun before the publication of Darwin's Origin of Species, though when that work appeared he read it. The reverse is often stated, but as a matter of fact there is a copy of the book in the library at Brünn containing manuscript notes by Mendel, and even a record that he considered that his work was helping to fill up gaps in Darwin's arguments. What is generally understood by Mendelism will be found in Chapters 10, 11, and 12, which form a summary both of what Mendel did and why he was doing it. After eight years of work the results were put into a paper entitled Experiments in Plant Hybridisation, which he read at the Brünn Scientific Society in 1865 to a completely puzzled audience. The proceedings of the Society were sent, in the course of an exchange of courtesy between learned bodies, not only to Vienna and Berlin, but to London, Warsaw, and St. Petersburg, but they attracted no attention whatever. Indeed, the scientific world did not become aware of Mendel until 35 years later. Dr. Iltis discovered the original MS. of this classic paper in a box destined for the flames.

So much has been written on Mendel's doctrines that the story of the researches will be familiar to many, but it is made more piquant by the revelation of Mendel's personality. He is usually thought of as a good old priest making pottering inquiries into the habits of bees and peas in a convent *potager;* he was a fighting mitred abbot, and a finished man of business.

devoted to tropical diseases rarely encountered in this country, while anxiety neurosis, which the practitioner will encounter every day, and probably more than once a day, should occupy a section of less than two inches. The reason is, no doubt, that the proportions of the matter in a text-book much used by students for purposes of revision are inevitably determined rather by the requirements of the examination paper than by the exigencies of practical life. In the more conventional departments of medicine, however, the student can safely turn to "Wheeler and Jack" as a reliable and lucid guide both for his examinations and in his practice.

Selected Writings of John Hughlings Jackson.

Vol. II. Edited by JAMES TAYLOR, M.D., F.R.C.P. London: Hodder and Stoughton. 1932. Pp. 510. 25*s.*

Hughlings Jackson's contributions to medicine ranged far beyond the field of technical neurology; how much farther can be gauged by turning over the pages of this second volume of "Selections." He was a master of both the abstract and the concrete, the subjective and the objective. Minute attention is paid to the stages and signs of optic neuritis, to the action of the intercostal muscles during surgical anæsthesia, and to the movement of the vocal cord when the recurrent laryngeal is stimulated; and from such studies in miniature, as though the observing eye were gazing down a clinical microscope, he moves away to another world, discussing with no less ardour of mind the factors of insanities, the application of evolutionary principles to the build and functions of the nervous system, the use of words and other symbols in mentation. Not content with such colossus strides over the realm of neurological and psychological science, he turns aside lightly to deal in whimsical yet penetrating fashion with punning and joking, in a memorable address. None is more revealing in respect of Jackson's personality; none more typical of his fine mental qualities. He tells us that sense of humour implies surplus intellect, and after illustrating the true implication of punning, as constituting a mild mental diplopia, he hints that his address on jokes is itself merely a big poor joke, yet something more also, for it has an intimate bearing on the study of mental symptoms in "serious diseases." No remark of his embodies a more suggestive truth.

A glance at the long bibliography published in this volume will show how much of Jackson's writings remain in their old format, how little, comparatively, has been chosen for reproduction. The possessor of these new publications can now read at will and ease the choice products of his genius; they form a Jacksonian thesaurus to be pondered over in the leisure hour; and their pages echo the voice and mirror the mind of the best-loved and most gifted among the neurologists of his time.

Ergot and Ergotism.

A Monograph. By GEORGE BARGER, F.R.S., Professor of Chemistry in Relation to Medicine in the University of Edinburgh. London: Gurney and Jackson. 1931. Pp. 279. 15*s.*

ERGOT has long been a subject of interest to physician, chemist, and pharmacologist. Since the middle ages, recurrent epidemics of ergot poisoning have been recorded in various parts of Europe. It has been employed in obstetrics since the seventeenth century, and for nearly 100 years chemists and pharmacologists have laboured to elucidate the mysteries of its active constituents. Everyone will welcome, therefore, a monograph by the discoverer of ergotoxine, who, in what he describes as "a happy partnership in research more than 20 years ago," made important contributions to our knowledge of the subject. Prof. Barger's book is wholly admirable. Little of importance published in Europe or the United States has been overlooked by him, and he has given us what we believe to be the most complete and best account of ergot and ergotism in the English language. The work is divided into six chapters, the first of which discusses the history and distribution of rye in various countries, its importance as an article of diet, its infection with *Claviceps purpurea*, the numerous designations of ergot, its obstetrical use in the eighteenth century, and its introduction into official medicine. The second deals with the two types of ergotism: the gangrenous and the convulsive. The former is easy to understand, for ergotoxine and ergotamine produce a prolonged constriction of the peripheral vessels. But until recently the convulsive variety was inexplicable, for none of the active constituents which had been isolated was found to be capable of producing the symptoms. Then Prof. E. Mellanby's work suggested the convulsive seizures were due to some unidentified neurotoxin, present not only in ergot but in rye itself, which acts only when there is a deficiency of vitamin A in the diet. Prof. Barger, commenting on the recorded epidemics of convulsive ergotism, points out that they afford considerable support for this view. The remaining chapters deal fully with the botanical, chemical, pharmacological and clinical, pharmaceutical and forensic aspects of ergot; and the whole is rounded off with an extensive bibliography and index of authors. The Dohme lectureship, instituted at the Johns Hopkins University to promote the development of a more intimate relationship between chemistry, pharmacy, and medicine, and held by Prof. Barger in 1928, has, indeed, fulfilled the object of the founder by leading to the publication of this important work.

Phantastica.

Narcotic and Stimulating Drugs: their Use and Abuse. By LOUIS LEWIN. Translated from the second German edition, by P. H. A. WIRTH, Ph.C., B.Sc. (Munich). London: Kegan Paul, Trench, Trübner and Co., Ltd. 1931. Pp. 335. 15*s.*

THERE is perhaps no subject which presents more difficulties to the pharmacologist than the action of drugs on the higher centres of the brain. Animal experiments, as a rule, give little or no information; and human consciousness is mysterious and almost incomprehensible. Yet chemical substances affecting consciousness are used by civilised and uncivilised peoples in all parts of the world. The history of the use and abuse of these stimulating and narcotic drugs, and the nature of their effects, are subjects of interest therefore, not only to the pharmacologist, but to physician, psychologist, and intelligent layman alike. All these will find the information they need in the book by Mr. Louis Lewin. Drugs capable of effecting a modification of cerebral function are classified by the author into five groups. The first he calls euphorica, or mental sedatives, of which the best known are opium and its alkaloids, and cocaine. The second is phantastica, or drugs of illusion and hallucination. This includes mescal buttons (*Anhalonium lewinii*) and Indian hemp. The third is the

de KuYPER'S HOLLANDS

Distilled from genuine malt liquor with the Juniper berry added. The advantage gained by distilling the berry with the spirit is the production of a preparation of Oleum Juniperi, mellow and free from irritating properties.

Oleum Juniperi is official in the British Pharmacopœia, and is described as carminative, anti-spasmodic, and a stimulating diuretic.

In this form, therefore, the oil of Juniper can be safely taken with regularity.

Distilled by the same family for 236 years.

Blutkrankheiten und Blutdiagnostik.

Fifth edition. By Dr. med. OTTO NAEGELI, Professor der inneren Medizin an der Universität Zürich und Direktor der medizinischen Universitätsklinik. Berlin: Julius Springer. 1931. Pp. 704. RM.89.60.

IN the eight years which have elapsed since publication of the previous edition of this well-known text-book, much new work on hæmatology, which calls for comment, has appeared. With his customary vigour and individuality the author discusses most of the recent advances in this branch of knowledge and has once more brought up to date the most exhaustive text-book that we know of on blood diseases and their diagnosis. Chemical, microscopic, and physical methods of examination; descriptions of cell elements, their morphology, embryology, physiology, and pathological alterations; and finally, descriptions and discussions of the diseases in which blood changes occur are all included. It is noteworthy that two pages of hæmatological nomenclature precede the text in this edition. A term is given, followed by the name of its author, the sense in which it is used, and the number of the page on which it is described. This innovation will be welcome to many who have not followed the controversies on this subject of the last thirty odd years. Among those who are better informed some will be found to protest, for example, against the following premature pronouncement: "Hämocytoblast (Ferrata). Theoretische Stammzelle der roten und weissen Blutzellen, morphologisch identisch mit Myeloblast. Neuerdings als Begriff aufgegeben. S. 276." Indeed from the first page of the preface, which includes a solemn warning against the teaching of Maximow, the author's bias is proclaimed, and throughout the volume no opportunity is lost of returning to this battle ground of the origin of blood-cells. Prof. Naegeli holds to his original views upon the dual origin of the leucocytes and in the sections on embryology and extramedullary myelopoiesis he answers the arguments which his opponents have brought forward in the last eight years. The great interest and value of this text-book are in no small measure due to the author's continual references back to genetical relationships of the cells under discussion, whether one agrees with his conclusions or not.

Among new clinical methods the blood sedimentation test is critically examined and its value is not considered to be very great. On the other hand, a method of estimating globulin worked out in the author's clinic is regarded as important in establishing the existence of infection and cachexia. Special stress is laid upon the distinction between megaloblasts and normoblasts, and upon the identification of pathological neutrophiles. Some of the most valuable additions in the present volume are the author's new classification of the anæmias, a much enlarged chapter on pernicious anæmia, and full accounts of the various forms of septic angina, including sections on agranulocytic anæmia. The illustrations in colour are lavish and excellent and a bibliography accompanies each section.

Journal of Pathology and Bacteriology.

THE May number (Vol. XXXV., No. 3, pp. 301–476) contains the following papers.—A Further Account of the Trinidad Outbreak of Acute Rabic Myelitis: histology of the experimental disease, by E. W. Hurst and J. L. Pawan (London and Trinidad). In Trinidad rabies causes a disease in cattle mistaken for botulism, and one in man mistaken for poliomyelitis; dogs are not concerned, and the infection is probably passed from cattle to man by the vampire bat. Full details are here given of the experimental inoculation of monkeys, and of the histology of the disease so produced. The histological details of human rabies are not as well known as they ought to be.—The Classification of Cancer of the Rectum, by C. E. Dukes (London). Cases may be divided into those confined to the wall of the rectum, those which have spread to extra-rectal tissues, and those which have in addition involved the regional lymphatic glands. The prognosis of the three groups is as would be expected.—The Pathology of Aneurysm: a review of 167 autopsies, by H. G. Garland (Leeds). This analysis of the aneurysms found in 12,000 consecutive examinations at Leeds brings out the great numerical preponderance of aortic lesions and the unimportance of syphilis in the smaller vessels. Many interesting details are given, and there is an ample list of literature.—A Malignant Melanotic Tumour of Ganglion Cells arising from a thoracic sympathetic ganglion, by W. G. Millar (Edinburgh). In a man of 34.—Medullo-epitheliomas of the Brain and Retina, by T. B. Davie (Liverpool). One of the brain (rare) and two of the retina.—The Isolation of Motile Organisms from apparently non-motile cultures of *B. typhosus*, *B. proteus*, *B. pestis*, *B. melitensis*, &c., by D. B. Colquhoun and J. Kirkpatrick (Glasgow). When grown on semi-solid media several organisms which are not motile on the ordinary solid or liquid media develop flagella and motility, or, having flagella already, become motile. It seems likely that the conditions of growth enable motile individuals to emerge from their non-motile populations and become manifest.—The Occurrence of True Bone within a Renal Calculus, by G. Stuart and K. S. Krikorian (Jerusalem). Some infective process causes an inflammatory condition in the submucous connective tissue which leads to bone formation. The bone then sloughs out into the lumen of the pelvis and forms the nucleus of a calculus.—The Effect of Carbon Monoxide and other agents upon the rate of Tumour Growth, by J. A. Campbell (London). Laborious experiments on mice show that chronic carbon monoxide poisoning stunts general growth and delays the growth of transplanted tumours.—The Interstitial Reactions caused by Various Dusts and their influence on Tuberculous Infections, by E. H. Kettle (London). Siliceous dusts which are effective in causing dangerous silicosis in man may be identified by their producing lesions in animals in which tubercle bacilli grow freely.—The Transmission of Fowl Tumours to Pheasants, by C. H. Andrewes (London). Three fowl tumours grew well in pheasants though serial transmission failed; three others did not grow.—Abnormalities of the Mouse Suprarenal, by R. Whitehead (Manchester). Varix found in examining 477 mice.—Fœtal Rickets, by J. P. Maxwell and C. H. Hu (Peiping) and H. M. Turnbull (London). Another clear example of fœtal rickets in the child of an osteomalacic mother dying three days after birth; full histological description and discussion.—Tumour Immunity. II. Antiserum Treatment of Spontaneous Mouse Carcinoma, by T. Lumsden (London). The euglobulin fraction of anti-cancer (man, rat, mouse) sheep sera can invoke or increase the resistance of a proportion of mice to their own tumours.—Fat Mobilisation in Starvation, by J. H. Dible (Liverpool). The fatty infiltration of the liver caused by starvation depends on the size of the fat depôts available.—A case of Periarteritis Nodosa in a syphilitic subject, by J. Gray (Aberdeen). A rare and accidental association.—Oxygen Poisoning in Rats, by A. E. Boycott and C. L. Oakley (London). Death is caused by massive pleural effusions.

Obituary notices of R. Stenhouse Williams and A. L. Urquhart.

THE LANCET.

LONDON: SATURDAY, MAY 21, 1932.

TOXÆMIA OF PREGNANCY.

Even to-day it is impossible to assure a healthy woman that she can face pregnancy without fear of toxæmia, and Prof. J. M. Munro Kerr[1] is right in saying that few ætiological problems more urgently need solution. Despite much research, we have not yet been able to dissociate cause and effect among the changes observed, for instance, in the blood and urine, and at least four theories still hold the field—the placental theory, the maternal theory, the fœtal theory, and the pressure theory. Nor are the inter-relations of the various disorders of pregnancy adequately understood. Many people regard albuminuria as the first stage in a process which, unchecked, may lead straight on to the eclamptic fit; on the other hand, G. W. Theobald in our columns last autumn was still able to argue that albuminuria is due to mechanical causes and is unrelated to the widespread havoc associated with eclampsia. The Aschheim-Zondek test shows clearly that chemical changes occur in the female organism from the first few days after conception, and Prof. Munro Kerr holds that the grave toxæmias are in line with the mild symptoms, such as morning sickness, which may appear very early in pregnancy. He points out that it is now a matter of exact knowledge that in the early weeks there is great endocrine activity, considerable destruction of the uterine mucosa, transport of syncytium and portions of villi by the circulation, and distinct alteration of the metabolism. The placenta is degenerating from the sixth month onwards, and the products of protein autolysis may then prove the "last straw" for a long-overburdened organism. To Prof. Munro Kerr pregnancy toxæmia is the resultant of a long struggle between the protective activities of the woman's organs and tissues on the one side, and the attacking forces of endocrine secretions, digested endometrium, and metabolic disturbance on the other. He urges his students to investigate the clinical and chemical features of early pregnancy, searching above all for the clue to morning-sickness.

Several investigations into the chemistry of normal and toxic pregnancy have been published within the last few months. Some are positive and some are negative. H. J. Stander,[2] recalling an increase in blood guanidine reported by Major and Weber in cases of arterial hypertension, has made routine investigations into the blood guanidine of his eclamptic patients and of normal pregnant women at term. He did not find in eclampsia any definite or marked increase in blood guanidine, nor did he find a hypoglycæmia. The eclamptic did, however, show an increased uric acid content in the blood and a decreased CO$_2$-combining power—a phenomenon noted also by Gordon King[3] in his survey of 33 cases in China. Stander concludes, from these observations and from clinical experience, that calcium therapy is not a rational measure in eclampsia. D. F. Anderson[4] has also been unable to ascribe any effect to calcium gluconate injections beyond saying that in the doses given they had no abrupt effect on the frequency of the fits. He definitely found subnormal serum calcium values (9 mg. per 100 c.cm. or less) in 82 per cent. of 44 eclamptic women he examined, but he also found low calcium values in 17 per cent. of 35 cases of normal pregnancy which he examined at full term, during labour, or shortly after delivery. While he regards the low concentration of calcium in eclampsia and pre-eclampsia as suggestive he does not think it can be definitely regarded as an ætiological factor; we are to consider it rather as a sign, just like the raised inorganic sulphur content of the serum, which may be as high as 3·6 mg. per 100 c.cm. in eclamptic cases but is not raised in other toxæmias or in normal pregnancy (D. F. Anderson and S. L. Tompsett[5]).

In his view that eclampsia is not caused by any renal lesion, Theobald finds a supporter in H. Acosta-Sison,[6] who has made a clinico-pathological study of 28 cases. She considers that the eclampsia toxin first stimulates and irritates the bulbar centre, which may be so sensitive that it is paralysed by a dose of toxin insufficient to cause organic lesions in the heart, liver, or kidney; though as a rule organic lesions accompany severe symptoms. If the dose of toxin is excessive, extensive lesions may be caused without any of the symptoms of irritation of the centre—e.g., high blood pressure, headache, and convulsions—because the centre is paralysed from the first. Her cases show that death can take place with no more severe injury of liver or kidney than a slight cloudy swelling. Nor was anything more than cloudy swelling of liver and kidney found by N. J. Berkwitz and N. H. Lufkin[7] in their cases of pregnancy paralysis—a condition for which they prefer the term "toxic neuronitis" and which they definitely link with the other toxæmias as a form of auto-intoxication affecting the nerve-cells and peripheral nerves. They have collected 38 published cases and added four of their own, and they regard the condition, although rare, as one of great severity, demanding immediate interruption of pregnancy. Prof. Munro Kerr's emphasis on the importance of morning sickness is justified by the fact that toxic neuronitis

Reminders and Suggestions

Products for use in General Practice

ADREPATINE A combination of Pluriglandular and Vegetable Extracts with Stovaine for the rational treatment of Hæmorrhoids.

Ointment: Tube with Canula—Suppositories: Box of 16.

HYPOTENSYL The active principles of Viscum (Gui) with Hepatic and Pancreatic Extracts for the treatment of conditions associated with High Blood Pressure.

Bottles of 50 Tablets.

IODOBESIN Iodalbumin with Pluriglandular Total Extracts. A safe and useful adjunct in the treatment of Obesity.

Bottles of 60 and 120 Tablets.

Gives good results in nearly all cases, whether of genital, thyroid, pituitary or undefined origin.

GYNOCALCION Calcium, Manganese and Phosphorus with appropriate Opotherapeutic Extracts for endocrin-sympathetic disturbances.

Bottles of 80 Dragees.

Supplied in two forms Gynocalcion M—for irregularities of the Menopause.
Gynocalcion P—for the troubles of Puberty.

MYCOLACTINE A combination of Bile Extract, Yeast, and Lactic Ferments for the rational treatment of Alimentary Toxæmias, Intestinal Stasis and Constipation.

Bottles of 50, 500 and 1000 Tablets.

Literature and Samples on request from

THE ANGLO-FRENCH DRUG CO., Ltd.,

with the syndrome of acromegaly, or acromegalic gigantism. The more common chromophobe adenomas produce mainly signs of pressure on the optic chiasm and other neighbouring structures; apart from interference with sexual function their manifestations of endocrine disorder are not usually conspicuous and consist chiefly of slight obesity, loss of hair and certain other changes in the skin—a slight degree of the so-called "hypopituitary" syndrome. Mixtures of the acromegalic and "hypopituitary" syndromes occur, and, though further histological work with special methods of fixation and staining is necessary, it is probable that the adenomas that produce them are composed of mixtures of chromophobe and acidophile granular cells.

In all this work, around which has accumulated a vast literature, little notice has been given to pituitary adenomas composed of basophile cells. Two tumours of this type were described by J. ERDHEIM[1] in 1903, but they were extremely small and were looked upon as pathological curiosities without clinical significance. During the past 20 years cases of a curious polyglandular syndrome have been recorded by ZONDEK, PARKES WEBER, and others in which the hypophysis was found to contain an adenoma, probably or certainly basophile in type, but the authors did not regard the tumour as the cause of the syndrome. Recently, however, the claim has been put forward by HARVEY CUSHING[2] that the basophile pituitary adenoma is a tumour that produces profound and specific symptoms. CUSHING has collected 12 cases of a disorder which is characterised chiefly by a peculiar type of adiposity, sexual dystrophy, hypertrichosis, vascular hypertension, and extreme weakness. The excess of fat is confined to the face, neck, and trunk, the limbs being spared; and the skin, which is often very dry, takes on a dusky colour and presents numerous lineæ atrophicæ, so that many of the patients, both male and female, look as if they were pregnant. In some of them ecchymoses occur, in others pigmentation, and some have glycosuria and hyperglycæmia. The patients are all young adults, they complain of backache and pains in other regions and ultimately of extreme weakness, and they are apt to die of intercurrent infections, to which they show little resistance. Necropsy reveals chronic nephritis and cardiovascular hypertrophy, and often osteoporosis of the skeleton, most marked in the spine. Various changes are observed in the endocrine glands, such as cortical hyperplasia of the adrenals and atrophy of the ovaries and testes.

In three of the cases collected by CUSHING a basophile adenoma was found in the anterior pituitary lobe, and in three others an adenoma of unspecified type. In two of the verified cases the histological diagnosis was made respectively by such authorities as H. M. TURNBULL and E. J. KRAUS. In the third case the diagnosis was made in life by H. M. TEEL, a pupil of CUSHING, and the basophile adenoma was no more than 2·5 mm. in diameter and was only discovered by serial sections of the whole hypophysis. In some of the other cases the pituitary was said to be normal, but in the absence of serial sections this cannot now be regarded as conclusive evidence against a pituitary tumour. All the tumours were small and none of them gave rise to pressure on the optic chiasm.

In ascribing this syndrome to basophilic adenoma of the hypophysis CUSHING, as he freely admits, goes contrary to recent experimental work which suggests that the sex-stimulating hormone of the hypophysis is secreted by the basophile cells. If this view be correct it would not be expected that tumours of basophilic cells would produce atrophy of ovaries and testes, as has in fact been found. This question must await solution, but all clinicians and morbid anatomists will agree that in endocrinology observations on the human subject should always be preferred to those on animals, and should indeed be marshalled in judgment of the application of experimental work to clinical concepts. The facts gathered together in this paper establish a fairly strong claim that in some of the cases, but not in all, the syndrome described was due to basophile adenoma of the hypophysis. Many will doubt, however, whether the syndrome is specific, in the sense that the syndrome of acromegaly is now known to be due only to an acidophile adenoma of the hypophysis. Two cases of pluriglandular disturbance were recently carefully described by O. LEYTON, H. M. TURNBULL, and A. B. BRATTON[3] and in these the causal lesion appeared to be a carcinoma of the thymus. In both cases there was adiposity of the face and trunk, and glycosuria. The second case especially resembles most closely some of CUSHING's cases, not only in external appearance, symptoms, and death from infection, but also in the necropsy findings of cardiovascular hypertrophy, hypertrophy of the cortex of the suprarenal bodies and of the thyroid gland. It is interesting to note that CUSHING refers briefly to a case described by WIETH-PEDERSEN, of Copenhagen, in which what was evidently a somewhat similar syndrome was found in association with a malignant adrenal tumour. In view of these cases the specificity of the syndrome described must for the present remain in doubt, but not, it is to be hoped, for long: for CUSHING's paper should stimulate clinicians and pathologists alike in their efforts to disprove or substantiate his claim.

HOSPITAL CONTRIBUTORY SCHEMES AND ANNUAL SUBSCRIPTIONS.—The Birmingham and Midland Ear and Throat Hospital reports that the contributory scheme was its chief source of income for 1931, annual subscriptions having fallen considerably since the institution of the scheme which, owing to a new method of allocation, contributed £1356 less than in 1930. In-patients numbered 1195, an increase of more than 10 per cent., and the average stay was 12·88 days. In addition, 623 patients were, by arrangement, admitted to St. Chad's Hospital. There were 8575 out-patients, a decrease of 500. It is pointed out that the resources of the hospital are "quite unequal to cope with the work," and an up-to-date building is declared to be "imperative."

appears about the third or fourth month in cases of hyperemesis; indeed the paralysis may be mistaken for inanition as the result of uncontrollable vomiting.

DIETARY SURVEYS.

THE direct experimental method has recently been applied with good effect to the science of nutrition, animals and less frequently groups of human subjects being employed to test the effect of variable dietetic factors on development and liability to disease. But another method of investigation is sometimes employed, consisting of a careful survey of the food actually consumed by selected groups of individuals over a definite period. If the subjects of such surveys are apparently normal healthy individuals it is assumed that the diets observed are more or less adequate. Moreover, it is possible from such studies to gain some information about the amounts of various food components habitually consumed by members of various classes of society, and by comparing these amounts with figures obtained in the laboratory for the food requirements of normal healthy subjects it may be possible to gauge roughly the prevalence of any marked degree of under-nutrition in a given section of society. CATHCART and his co-workers have been engaged in a series of surveys of this type, and have just published the results of their inquiry into the diet of families in Cardiff and Reading.[1] The inquiry was limited to working-class families, and comprised a total of about 370 individuals in each town. As in their previous study, carried out at St. Andrews, they found the average daily caloric value of the diets ranged fairly close to the accepted figure of 3000, and the amount of fat consumed was in both instances distinctly higher than the generally accepted average—namely, 113·6 g. in Cardiff and 100·8 g. in Reading. Special interest is attached to the analysis of the poorest diets. The mean value in 8 families in Cardiff and 12 in Reading was less than 2500 calories, and in three instances was less than 1800. It was found that this shortage of food was not occasioned solely by the smallness of the income, but arose partly through the improvidence or incapacity of one or the other parent. It appears that with very restricted incomes a distinctly smaller proportion of the weekly wages is devoted to the buying of food in these English towns than in Scottish towns, which fact is largely accounted for by the higher rents paid in the English towns. Special attention was devoted to the physique of the children belonging to the families under observation. It did not appear that any serious degree of malnutrition existed among them, although the numbers examined were too few for any decided opinion to be formed on this point.

The practical use to which dietary surveys can be put is illustrated by a circular recently issued by the United States Department of Agriculture regarding midday meals for pre-school-children.[2] The object of the circular is to suggest suitable menus for young children attending day nurseries and nursery schools. The menus are carefully constructed so that they furnish approximately the same amounts of the main food constituents and the same total energy value. These standard quantities were arrived at after a consideration of reliable surveys of the diets of normal healthy young children brought up in private families with varying incomes. Some of the main findings of four such surveys are reproduced in the present report. The mean energy value of diets of children aged 2 to 3 years varied in the different surveys between 1200 and 1400 calories; of those aged 3 to 4 between 1330 and 1500 calories; and of those aged 4 to 5 between 1430 and 1720 calories. In some of these surveys the intake of calcium, phosphorus, and iron was estimated as well as that of protein, fat, and carbohydrate, but the quantities of these mineral elements allowed in the proposed dietaries are based rather on previously published individual metabolism experiments than on the results of such surveys. Attention has been paid to the vitamin content of the diets, and free use is made of milk, eggs, salads, fresh vegetables, and cod-liver oil. The general plan of the scheme is to provide at the nursery school one-half of the estimated daily requirement of protein, phosphorus, and total energy, and rather more than one-half of the calcium and iron needed. The average cost of the raw materials for meals constructed from the proposed menus and actually served at one particular institution worked out at 17 cents (8½*d.* at par) per child per day during the first half of 1930, individual menus costing from 11 cents to 25 cents (5½*d.* to 1*s.* 0½*d.*). These figures are certainly very much higher than some recently quoted in the report[3] of the Advisory Committee on Nutrition, as representing the actual expenditure on children's food allowed by certain of the public authorities in Great Britain. From a qualitative point of view the recommendations of this committee agree well with those of the compilers of the American report.

◆

A NEW PITUITARY SYNDROME.

TUMOURS of the pituitary gland have always excited great interest because of the widespread disturbance that they produce both in the endocrine system and in other parts of the body. With few exceptions they are adenomas arising in the anterior lobe, a structure which is composed of three types of cell, chromophobe, acidophile granular, and basophile granular cells. Of these only chromophobe and acidophile cells have hitherto been encountered in tumours. Adenomas composed wholly or mainly of cells resembling acidophile cells of the normal gland are associated ith the syndrome of acromegaly, or acromegalic igantism. The more common chromophobe denomas produce mainly signs of pressure on the ptic chiasm and other neighbouring structures; part from interference with sexual function their ianifestations of endocrine disorder are not sually conspicuous and consist chiefly of slight besity, loss of hair and certain other changes n the skin—a slight degree of the so-called "hypo-ituitary" syndrome. Mixtures of the acromegalic nd "hypopituitary" syndromes occur, and, though urther histological work with special methods of ixation and staining is necessary, it is probable hat the adenomas that produce them are composed f mixtures of chromophobe and acidophile ranular cells.

ANNOTATIONS

ROBERT BOYLE.

A DELIGHTFUL book[1] about "that pious admirable Christian, excellent philosopher, and my worthy friend, Mr. Boyle" as John Evelyn calls him in his diary, has been written by Prof. Fulton as a contribution to the *Proceedings* of the Oxford Bibliographical Society. We wonder how many people know Robert Boyle's claims on the gratitude of the scientific world. He was one of the outstanding figures in the history of science, an ardent experimenter and a prolific writer. He made a greater number of variety of discoveries than perhaps any one man will ever make again; weighing the air, the thermometer, the barometer, freezing mixtures, the gas laws, chemical elements, phosphorescence, electricity are all intimately associated with his name. And between 1659, when he published "Seraphick Love" and 1695 when "A free discourse against swearing" appeared, about 40 books of his were printed as well as a number of papers for the Philosophical Transactions of the Royal Society; he had written also a considerable mass of manuscript which was destroyed in 1688 by the breakage of a bottle of sulphuric acid. He was not a good writer—discursive and not always very clear, and his contemporaries made fun of his prolixity; his arguments were not improved by his habit of making considerable additions and alterations when his books were half printed. But his public preferred his matter to his manner, and he must have been widely read, for many of his works went into several editions in English with latin versions for continental consumption. His scientific works are more or less well known—"The Spring and Weight of the Air," "The Sceptical Chymist," "The Relation between Flame and Air," &c.—though they still wait a detailed synthetic examination in the light of modern knowledge. But his general and theological writings are unfamiliar, and there are a good many of them. "Occasional Reflections" is a volume of essays or sketches of country life in Dorset; "Seraphick Love," a treatise on sacred devotion with some remarks on the profane sort; "The Excellency of Theology" rebukes his scientific friends for their rationalistic outlook; in "Possibility of the Resurrection" he considers what can happen to a man who has been eaten by a cannibal. In the appendix is a list (1692–1929) of those who have preached the annual sermons which he endowed "for proving the Christian Religion against notorious infidels—viz., Atheists, Theists, Pagans, Jews, and Mahometans, not descending lower to any controversions that are amongst Christians themselves." He also provided the funds for an Irish translation of the Bible and promoted a scheme for a Turkish version. Prof. Fulton, whose work is published in the *Proceedings* of the Oxford Bibliographical Society (iii., pt. 1) as well as in book form, ends with a catalogue of Boyle's elegies and biographies, though we cannot discover whether there really is a monument somewhere which describes him as "the Father of Chemistry and the nephew of the Earl of Cork."

The *Proceedings* of the Oxford Bibliographical Society, with its headquarters at the Bodleian, are issued annually to members of the Society, and copies of this part, we understand, may be obtained at 10*s.* each through a member of the Society. An off-print of Prof. Fulton's charming essay has been made for the author, for presentation purposes.

[1] A Bibliography of the Honourable Robert Boyle. By J. F. Fulton, M.A. Oxf., formerly Fellow of Magdalen College, Oxford. London: Oxford University Press. 1932. Pp. 172.

MODE OF ACTION OF VITAMIN D.

IRRADIATED ergosterol, when given in large doses to animals, causes a marked hypercalcæmia. The mechanism by which the hypercalcæmia is produced is not completely understood. There is dispute indeed over the important question of the source of the excess serum calcium. Does the parathyroid mechanism play a part? Jones, Rapoport, and Hodes (1930), Harris (1930), and Dixon and Hoyle (1928), conclude that the excess serum calcium which follows vitamin D overdosage is derived from the food, and that the vitamin increases absorption from the gut. In their last work Harris and Innes (1931) state that the excess calcium of the serum may be derived from the bones provided that the dosage of irradiated ergosterol is sufficiently large and the amount of the ingested calcium is inadequate. In face of the reports of many workers as to the effect of large doses of irradiated ergosterol in producing decalcification of the skeleton the view that vitamin D increases calcium absorption must be carefully scrutinised.

There is almost complete agreement between the chemical and morbid changes which follow the administration of large doses of parathormone and of irradiated ergosterol (Taylor, Weld, Branion, and Kay, 1931). Further, several workers have demonstrated that large doses of the parathyroid hormone cause decalcification of bone. Harris and Innes (1931) state that bone calcium is the sole source of the extra calcium resulting from parathormone administration, but draw a distinction between the action of the hormone and of irradiated ergosterol when they conclude that the latter but not the former increases calcium absorption. Having in mind the work of Hunter and Aub (1927) concerning the effect of parathormone upon the excretion of lead, Taylor and Weld[1] set out to determine whether or not irradiated ergosterol had an effect comparable to parathormone in ridding the body of lead. Cats were given daily, up to fifteen days, 15 mg. of lead acetate in solution. The dose was delivered by a syringe into the back of the mouth. A period of three weeks was allowed to elapse before administering the irradiated ergosterol in order to permit the daily excretion of lead by the bowel and kidney to reach a steady level. The administration of large doses of irradiated ergosterol at the end of this time caused the excretion of lead in the urine to mount rapidly and in some instances to increase by several hundred per cent. The fæcal excretion of lead showed little change. The appearance of large quantities of lead in the urine, and the increased urinary excretion of calcium under the influence of vitamin D indicate that the urinary lead and the associated calcium are derived from the bones rather than from the intestinal tract.

Dr. Harris in our last issue contends that the available evidence indicates rather that the parathyroid secretion and vitamin D normally function separately and independently, their effect on the blood calcium or phosphorus being only supplementary. He points out that it must be borne in mind that most past work on parathyroid function has been carried out on adult animals, sometimes on calcium-free diets and principally with very large overdoses of the hormone. The conditions, there-e, have not been comparable with those employed investigations of the action of vitamin D. He lds that the occurrence in common of such normalities as calcareous deposits in soft tissues d high urinary calcium, which is also used as an gument for the supposed identity of hyper-rathyroidism and hypervitaminosis, could be counted for as readily by regarding them as a cessary feature of the hypercalcæmia per se, ought on independently by the two disorders.

FUNCTIONS OF THE CAROTID BODY.

SOME important discoveries concerning the carotid ody are described by Prof. D. Danielopolu, of ucharest, and collaborators.[1] By observation and xperiment on human beings and animals they have cceeded in showing that the carotid reflex is (as hey express it) amphotropic in action; that is to ay, its effect may be pressor, depressor, or disso-iated, the reflex being produced via the two ntagonistic groups, the predominant effect being n the inhibitor. This information should help to xplain the conflicting results observed in experi-nental work and in pathological conditions affecting he carotid body. It was Czermak who first found hat compression of the vasculo-nervous bundle in he neck produced a slowing of the heart-beat, and Danielopolu who in 1920 pointed out that although the vagus was accessible to compression throughout its course in the neck yet the slowing effect was only obtained by direct compression of the carotid ganglion. In 1923 Hering showed conclusively that this cardiac effect was not a vagal effect, but a sino-carotid reflex; but he regarded the reflex as purely pressor in action—a parasympathetic stimulation. It was not until the results of the research of Danielopolu and Proca in 1924, and Danielopolu, Marcu, and Proca in 1927 were made known that it was realised that compression of the carotid ganglion produced a simultaneous stimulation of both the parasympathetic and sympathetic systems, and that the normal condition of tone of the carotid ganglion reflex was depressor—that is, the inhibitor action predominated in the two antagonistic effects. And further that in pathological conditions such as lesions of the heart, vessels, or nerves because of the modification of the tone of the vegetative system, the reverse result might be observed—namely, an excitation effect as a result of the predominance of the sympathetic. This latter result, which had been noted even in normal subjects, could never be explained on Hering's conception, but was easily understood if the hypothesis of amphotropism was accepted. Danielopolu and his colleagues now describe a number of experiments in proof of their hypothesis, and one of these may be quoted. In 1927 they published the fact that excitation of the carotid ganglion had an influence on the cerebro-spinal system in some subjects, and could produce convulsions. On this finding it was suggested that bilateral section of the nerve-fibres running to the carotid ganglion should be practised in cases of epilepsy, and this was done in three cases. The researches of Hering, confirmed by other workers, had shown that section of the nerve supplied by the glossopharyngeal to the ganglion produced a condition of tachycardia and chronic hypertension. If the carotid ganglion affected solely the parasympathetic system, and all the nerves running to it had the effect of the nerve of Hering, then bilateral section of all nerves should have produced the same effect as section of the nerve of Hering—namely, a tachycardia and a chronic hypertension. This, however, was not found to be the case, for in the three epileptics in whom this section of all the nerves was done, the tachycardia and hypertension did not develop. The absence of these phenomena constituted a further proof of the amphotropism of the tone of the carotid ganglion reflex.

REFLEX ACTIVITY IN THE NEW-BORN.

OF late years the objective study of infantile behaviour has brought to light many new facts; but their interpretation is beset with difficulties. One of these is that the neural mechanisms of the young infant are so labile that the reactions of each individual may alter considerably in a short period. In an investigation conducted at the Normal Child Development Research Clinic of the University of Pennsylvania, by Dr. Beverly Chaney and Dr. Myrtle McGraw,[1] an attempt has been made to estimate the variations which take place in the first few weeks of life, by comparing the reactions of a group of infants in the first few minutes after birth (referred to as partunates) with those of another group none of whom were more than ten days old (neonates). The authors also endeavoured, by recording the infants' responses in detail, to throw some light on the remarkable diversity of opinion expressed by different observers on certain reflexes, particularly the plantar, in infancy. All the infants examined were passed as in "good normal condition" by the accoucheur. The first group of 25 partunates was examined immediately after division of the umbilical cord. The various events in the delivery were previously timed and recorded, in case the duration of any of them might be correlated with a particular effect upon the infant. The reactions which were examined comprised the deep and superficial reflexes; sucking, grasping, blinking; pupillary reflexes and certain postural reflexes. A maximum of five successive stimuli was given for each reflex, and if no response was elicited by them it was regarded as absent. The most striking fact emerging from comparison of the two groups is that a larger percentage of deep reflexes was obtained from the partunates than from the neonates, whereas a much larger percentage of superficial reflexes was obtained from the neonates. Chaney and McGraw remark, somewhat paradoxically, that "most partunates were in a state of general muscular hypotonia, and this seemed to facilitate responses to tendon stimulation." The abdominal reflexes were present in a third of the neonates, but in only one partunate. As a general rule there was only a slight tendency for the responses to increase with successive stimuli; it appeared that repetition did not materially increase the probability of a response. The plantar reflex was studied in great detail, no less than 16 modes of response being observed and recorded. Plantar flexion of the toe was rarely seen. While a typical Babinski reflex was not often seen, dorsiflexion of toes in combination with other movements was the rule in both groups. In the neonates some form of dorsiflexion was present in 96 per cent. of cases. Sucking reflexes, elicited by inserting a rubber nipple into the mouth, were present in all but one of the neonates, but in only 16 per cent. of the partunates. The typical response of the latter was a biting movement of the jaw. A very significant difference between the groups was found in the grasping reflex, which was poorly developed in the partunates. A perceptible grasp was only recorded in 28 per cent. of the latter, as compared with nearly all of the neonates. The investigators draw attention to the variability of all reflex responses in the new-born, the variation increasing with the complexity. On the other hand, in those which have become established, such as the plantar reflex, there is nearly always a response of some kind, and its total absence should suggest a pathological condition.

[1] Danielopolu, D., Marcu, I., Proca, G. G., and Aslan: Presse Méd., March 30th, p. 489.

[1] Bull. Neurol. Inst. New York, March, 1932, p. 1.

These experimental studies are of considerable interest to the pædiatrist, and support the common medical experience that the nature of reflex responses in young infants is of little clinical significance. They also suggest that there is nothing more than a superficial resemblance between the normal infantile responses and the pathological responses met with in adults.

CINEMATOGRAPHY OF MENTAL DEFECT.

THE comprehensive system of still photography in use at the Fountain Mental Hospital is now being supplemented by cinematography, with its obvious advantages for the recording of movement, expression, and gesture. The films shown by Dr. Noel Burke to the Section of Psychiatry of the Royal Society of Medicine on May 10th represented the first prints of the method as used at the hospital and they fully proved its value in the demonstration of various forms of mental defect. The first was a study of movements made by the younger defectives of the lower grades. Examples were shown of the simple movements, such as grimacing, head-rolling, and body-rocking, leading up to quite complicated movements of head and hands and body. These restless cases were contrasted with two children who sat apathetic and almost motionless throughout the exposure. The next film was in two parts, and gave a detailed study of each type of defective, showing the essential physical features and the behaviour peculiar to each. It began with pictures of some score of mongolian imbeciles, both singly and in groups and continued with examples of microcephaly, hydrocephaly, nævoid amentia, and nodular sclerosis. The second part was devoted to neurological cases, and showed identical twins with the same ophthalmoplegia, a full study of a case of torsion spasm, and others of diplegia, athetosis, and post-encephalitis. The last film, of treatment and training, showed the various stages of education of manual ability, leading up to useful hand-work, and of combined movements leading to complicated action dances and group behaviour. The band, formed of high-grade patients from the Darenth Training Colony, was seen playing to the children and adults of the Fountain Hospital, who responded with evident pleasure by attention, rhythmic movements or actual dancing. A picture of a summer fête, with Punch-and-Judy show and the children dancing, swinging, receiving presents, wearing paper caps, and blowing toy trumpets, concluded the demonstration. In the subsequent discussion, Dr. A. F. Tredgold called attention to the suggestive similarity between some of the movements shown in the first film and those typical of dementia præcox. He believed that the latter condition and mental deficiency were closely related. Both he and Dr. Letitia Fairfield discussed the occurrence of so-called mongolian characteristics in normal people, and their tendency to disappear in defectives of this type who reach mature years. Dr. Fairfield had noticed that the nævoid cases seemed to be affected always on the right side. She also commented on the happy appearance of the patients shown in the film, as well as of their nurses, and on the improvement that 'proper' care had produced compared with the conditions she had previously seen when certifying the same children. Dr. R. M. Stewart spoke on a number of details arising from the demonstration, and gave some suggestions to explain the movements that had been shown on the screen. Lastly Sir Robert Armstrong-Jones recalled his long experience at Earlswood, and discussed the difficult problem of the borderline child who is seen in the children's courts and thence referred for an opinion on the mental factors in his case.

THE DETECTION OF ADDED WATER IN MILK.

THE report of the Lancashire public analyst, Mr. G. D. Elsdon, for 1931 shows that great care is observed in that county to play fair by milk vendors. It has taken some 60 years, says Mr. Elsdon, to provide the methods capable of solving this problem and, if it is not now actually solved, we are at any rate in a very much better position to give an opinion than when the Sale of Food and Drugs Act was passed in 1875. It will be recalled that there is no legal standard for genuine milk, but that, according to the Sale of Milk Regulations, 1901, any milk which contains less than 3 per cent. of fat or 8·5 per cent. of solids-not-fat is presumed, until the contrary is proved, to be not genuine. All that the regulations do is to enable the prosecuting authority to describe such a milk as adulterated and to put the onus of proof to the contrary on the defendant. A milk which contains less than 8·5 per cent. of solids-not-fat is not necessarily adulterated and one which contains more than 8·5 per cent. is not necessarily genuine. This is readily appreciated when we read that the average of all the 59,118 samples, including those adulterated, taken in Lancashire during the last 22 years showed 8·89 per cent. solids-not-fat, whilst 180,000 samples in other districts averaged 8·86 per cent. In the case of all deficient milks in Lancashire an appeal-to-cow sample is obtained before going into court and records of these appeals, which are available since 1903, show that the proportion of total milk samples naturally deficient in solids-not-fat has been only 1 in 480. The appeal to the cow has been invaluable in separating naturally deficient from watered milks. The latest addition to the means of securing justice as between producer and consumer is the freezing-point test. It has been found that the freezing-point of genuine milk is its most constant known property, being depressed below 0° C. by about 0·54°. Thus the average depression of the freezing-point in 211 genuine milks examined in the county laboratory during the last three years was 0·543° and no genuine milk has ever had a value below 0·530°. Among 60 appeal-to-cow samples taken in 1931 the least depression was 0·536°. Mr. Elsdon considers that, though the average depression for genuine milk is above 0·540°, no sample should be considered as watered on the evidence of the freezing-point alone, unless the value falls below 0·530°. In several cases during 1931 an appeal-to-cow sample had apparently a freezing-point indicating added water, but in all an explanation was forthcoming. In one the sample was obtained on a dark morning with inadequate supervision and further samples, two days later, gave depressions of 0·547° and 0·549°; whilst in the others the test was the agent in discovering a leak in the cooler. Mr. Elsdon sums up by saying that the indications of the test were never in doubt during the year. With practice and an apparatus, including standardised thermometers, costing about £15, accuracy, he says, to two-thousandths of a degree, which is more than sufficient for the purpose of detecting the addition of small percentages of water, can be obtained. He further states that the method is becoming increasingly popular amongst public analysts in this country and he enumerates countries abroad where it is used officially or semi-officially.

THE ROYAL SOCIETY'S CONVERSAZIONE.

AMONG the exhibitors at the conversazione of the Royal Society on May 11th, the laboratories of the Imperial Cancer Research Fund showed examples of vital staining. Fibroblasts of embryonic and adult tissue of the mouse, growing in vitro, segregate granules of trypan-blue, but cell death results in a diffuse staining. Sarcoma cells, on the other hand, do not segregate the dye, but take it up by active phagocytosis. This failure to segregate acid dyes, such as trypan-blue, appears to distinguish cancer cells from the cells of normal tissues, and the exhibit demonstrated this difference both in killed preparations of vitally stained cells and in living cultures of malignant and non-malignant cells. The killed preparations were post-vitally stained cultures to which trypan-blue had been added during life, and included mouse sarcoma, the filtrable tumours of the fowl, mammary carcinoma of the mouse, and tar carcinoma cells. The living cultures included similar tumours, and also the normal cells of *Salamandra maculosa* vitally stained with acid and basic dyes. With Dr. R. J. Ludford's generous explanations the preparations became intelligible even to those ignorant of cytology. Dr. W. Cramer and Dr. Ludford showed also a series of slides demonstrating the effect of radium on malignant growths. Experiments in mice show that when a radio-sensitive tumour of standard size is irradiated with a dose sufficient to produce its regression immediate inoculation of the tumour cells into fresh hosts will result in the development of new tumours. If the inoculation of tumour cells is not performed until several days after irradiation, no new tumours are produced. The tumours formed from the inoculation of a recently irradiated tumour, however, grow more slowly and show a lower percentage of "takes" than those obtained from the inoculation of non-irradiated tumours. The regression of a tumour after irradiation appears to be due to an injury inflicted not only on the tumour cells, but on the tissues of the tumour bed; the process of repair and fibrosis of the normal tissues plays an important part in the destruction of the tumour. This process was shown clearly in Dr. Cramer's collection of slides, while the action of radium on the actual tumour cells was demonstrated in another series of slides shown by Dr. Ludford. The immediate action on the tumour cell appears to be on the mitochondria, which become vesicular; mitosis is inhibited, but after a time the cells increase in size. With slowly growing mammary carcinoma this enlargement is great, and masses of secretion appear in the cells. With more rapidly growing tumours there is a wave of abnormal mitosis and ultimate degeneration.

The National Physical Laboratory, in an exhibit on the technical applications of X ray crystal analysis, included the result of an investigation into the crystalline structure of teeth. The enamel is almost entirely crystalline and the dentine contains crystalline material, the crystals in both cases being composed of apatite. In dentine the crystals are arranged at random, but in enamel they tend to have their axes parallel to each other. In dogs the axes of the crystals are perpendicular to the surface of the tooth, whereas in man the axes of the crystals are at an angle to the surface. It is possible that this may have some bearing on the greater durability of dogs' teeth, but this aspect has not yet been fully investigated.

Vitamins still have their place in the sun, and the National Institute of Medical Research was showing the method of production and the biological properties of calciferol (crystalline vitamin D). From the Lister Institute Prof. J. C. G. Ledingham demonstrated preparations to illustrate the association of elementary bodies with the lesions of vaccinia and fowl-pox, their agglutination by the serum of virus-infected bodies, and the presence of the same bodies in centrifugalised virus filtrates and virus cultures. Other exhibits included an interesting experiment made at the John Innes Horticultural Institution on the X ray treatment of *Primula sinensis*. Attempts are being made to induce chromosomal and gene mutations, and the inheritance of any induced abnormality is being studied. Samples of moistened seed treated with varying doses of X rays showed considerable somatic variation on germination. The Cambridge Instrument Company, Ltd., provided a smoke recorder, which differs from previous instruments in depending, not upon transmission, but upon diffraction of light from the dust particles, and which is held to be more accurate on that account. It is intended for use in chimneys, but it can be used equally well for air, and even for liquids, though this side has not yet been developed. Robert Hooke's hygroscope, an instrument—of which no original is known to exist—to show "the driness and moisture of ambient air," had been lovingly reconstructed by Mr. George H. Gabb. It depends for its action on the hygroscopic properties of the beard of the wild oat.

TRAFFIC IN DANGEROUS DRUGS.

THE advisory committee on traffic in opium and other dangerous drugs has reported to the council of the League of Nations on the work of its fifteenth session. Some 47 ratifications of the Geneva Convention of 1925 have now been deposited. The more recent Convention of 1931 for limiting the manufacture of narcotic drugs has been signed by some 45 Powers, and moreover, it has been ratified by the President of the United States. While the statistics of manufacture of morphine, heroin, and cocaine furnished by the several producing States show considerable reductions during the last five years, there is nevertheless a vast amount of illicit traffic still carried on. The United States delegate declared that "enormous quantities of opium and of manufactured drugs coming from Turkish ports had been seized in the States." Inasmuch as Turkey is about, at long last, to accede to The Hague Convention of 1912 and to the Geneva Convention of 1925, improvement is anticipated in illicit exports therefrom to Egypt, Europe, and America. It was stated by the Indian delegate that the area now under the poppy in India is but one-fifth of what it was in 1913 and that the export of opium for smoking had been reduced in 1930 to 4882 chests against 12,231 chests in 1919. It is anticipated that such exports will cease altogether in 1935, and that the opium produced in India will thenceforth be used only for internal consumption and for transmission to England for medical and scientific purposes. The exports of opium from Persia appear to be greatly in excess of the certificated amounts; during the period from Dec. 1st, 1930, to Dec. 31st, 1931, some 4239 chests of opium, weighing over 300 tons, were exported from Bushire, sometimes in such a way as to "ensure that the loading of cargo should escape observation." In accord with resolutions passed by the Council and the assembly of the League the advisory committee, in conjunction with the secretariat, is drafting two questionaires dealing with the limitation of the cultivation of the opium poppy and the coca leaf, respectively, to be addressed to the producing countries of these raw materials from which most of the "dangerous drugs" are derived

THE DIAGNOSIS OF ERYTHROMELALGIA.

Too little is known about the conditions associated with vascular disturbances in the extremities. We have not even a satisfactory nomenclature and the text-books are apt to dismiss the different types in a short sentence. G. E. Brown,[1] of the Mayo Clinic, believes that accurate studies of surface temperature in relation to subjective distress will allow of the separation of these disorders into two groups—those with and those without local vasodilatation. He has made a particular study of erythromelalgia, and he holds that this distinction is fundamental in diagnosing the disease; thus he says that the diagnosis is warranted only in the presence of increase of vasodilatation which parallels the degree of pain or distress, when the condition is bilateral and intermittent, and when there is no primary or associated disease which would provide an explanation. He found that with one exception his series of ten cases of "true primary erythromelalgia" exhibited four of the five basic signs originally described by Weir Mitchell. These were: bilateral burning pain in the extremities; sharp increase of local heat in the affected part with redness, flushing, or congestion varying in degree; production and aggravation of the distress by heat and exercise; and relief by rest, cold, and elevation. The fifth sign, non-amenability to treatment, had some exceptions, since application of radium sometimes gave relief; but whether this relief would be lasting it was too early to say. In connexion with the surface temperature of the affected limbs, Brown was able to establish the interesting fact that when the temperature reached 33° or 34° C. pain usually became evident; conversely relief came when the temperature fell below 33° C. Augmentation in arterial pulsation and in the rate of loss of heat gave further evidence of the high degree of dilatation of the arteries. Great stress is laid in diagnosis on excluding other types of cases suffering from excessive vasodilatation in the hands and feet—as, for example, Raynaud's disease where the underlying disturbance is vasospastic rather than vasodilator, and thrombo-angeitis obliterans, where there is a definite pathological change in the vessel walls. There is no doubt that these vasomotor dystrophies are of importance to those who suffer from them, and it is no exaggeration to say that they may give endless annoyance and discomfort and occasionally such severe pain as to make a patient's life a burden. One of Brown's series, a man aged 57, had suffered from a bilateral burning pain in the feet for 20 years and in the summer months got relief by walking all day in the wet sand on the banks of a river. Wearing shoes or otherwise covering the feet caused excruciating pain, and this patient committed suicide two years after he left the clinic.

EPIDEMIOLOGY OF MEASLES.

THE Health Section of the League of Nations have reviewed [1] the incidence and death-rate from measles in certain countries between the years 1919 and 1931. In most European countries 1929 was a year of light mortality, and in most of them, too, the mortality rose in 1930, though it did not exceed the average of the ten previous years. In measles, however—unlike small-pox and diphtheria for example—it is exceptional for many countries to show parallel mortality-rates. Each of them is undergoing alternating epidemics and "hypo-endemics," and the national differences between the maximum and minimum mortality-rates may vary considerably. In England the maximum is said to be three and a half times higher than the minimum, in Germany the proportion is 5 to 1, and in Scotland and Denmark it is 17 to 1. The smaller the population the larger, as a rule, the difference, because in countries with larger populations there is a relative compensation between the operation of hypo-endemics and epidemics. A seasonal influence is observable both in incidence and mortality; thus a graph illustrating the incidence of measles in Denmark shows that the minimum mortality is regularly in September. In most countries where measles is endemic the maximum incidence is observed at the end of winter and in spring. Between 1926 and 1931 92 per cent. of the annual maximums of morbidity registered in 18 countries was between December and May, and only 8 per cent. between June and November. In Spain, Portugal, and Egypt, and less clearly in Mexico, the maximum mortality tended to be during the hot season, while in the countries of eastern and northern Europe, which have a severe winter, the rise in the mortality- and morbidity-rates took place in November and December—earlier than in most European countries. As might be expected, in view of the time which the complications of measles take to cause death, the mortality curve shows a slight lag behind the incidence curve—a lag of about three weeks. Thus morbidity reaches its maximum in most countries in March, and mortality in April. The variation during the year in the case-fatality rate amounts only to about 1 per cent. The mortality-rate from bronchopneumonia runs a course strikingly parallel with the mortality-rate from measles. It is about a month in advance of the measles curve, reaching a maximum in March and a minimum in August. If the case-fatality rate of measles is calculated from the number of cases notified during one month and the number of deaths during the following month, it is evident that measles takes a graver form when bronchopneumonia is more prevalent. Carriers of streptococci and pneumococci run a greater risk than other people.

MEMORIAL GARDEN, ST. BARTHOLOMEW'S HOSPITAL. Miss Peggy Salaman last week opened a memorial garden presented to the nurses by Sir Herbert and Lady Cohen in memory of their son Nigel, a student at the hospital, who was killed while flying.

SPECIAL ARTICLES

REDUCTION OF MARRIED WOMEN'S SICKNESS AND DISABLEMENT BENEFITS.

By Mabel L. Ramsay, M.D., F.R.C.S. Edin.

Twenty years' experience of the working of national health insurance has at last revealed certain truths that might have been anticipated from common knowledge—i.e., that it was to be anticipated that the sickness-rate amongst women workers would be greater than amongst male workers for the reason that a certain large percentage of the women workers would be married. Marriage for the male worker usually means that his health is better looked after than before marriage. To the woman worker marriage adds to the usual illness of single life its own duties plus those of pregnancy and diseases associated thereto.

Hence I feel it was a wrong policy from the start to base an insurance scheme for women on a lower weekly premium than for men, even if the men's fund bears, as it does, the cost of maternity benefit. A business insurance company to-day charges for an all-sickness policy terminable at 65 at least 25 per cent. more to a professional woman, and excludes illness associated with pregnancy.

MORBIDITY STATISTICS AND THEIR LESSONS.

The Government Actuary, in his report[1] on the financial provisions of the Bill now before Parliament, shows a continuous rise in sickness claims from 1921 to 1927 (due no doubt to post-war depression) which have exceeded the provision made in the estimate by 17 per cent. for unmarried and by 30 per cent. for married women. Disablement claims for the same period showed an excess of 19 per cent. for unmarried and 71 per cent. for the married. Taking all societies together an additional sum of £850,000, not covered by insurance premiums, has had to be found by the Treasury—namely, for unmarried women, £430,000, for married women, £420,000. At the last valuation the numbers of unmarried insured women were given as 4,293,000, those of married insured women 1,132,000. Each individual unmarried woman has cost the fund 2*s*., and each married woman 7*s*. 6*d*. more than the estimate. Hence, Sir Alfred Watson proves quite easily that insured women as a class are receiving more than the insurance premium received can pay for.

In January last a report was issued by the Department of Health for Scotland, setting out a morbidity statistics scheme which is well worth perusal. This report states that statistical examination of doctors' certificates issued in nearly every area shows a well-defined grouping of practitioners round the area average, with a few practitioners conspicuously outside the group. This would appear to indicate a fair measure of consistency in the certification methods of practitioners with panels similarly constituted. Certain facts emerge from an analysis of the figures collected during the year July, 1930–31. In this year the incidence of incapacity in single women was equal to that found in men, but married women are certified as incapable of work twice as frequently as men or single women. Duration of illness irrespective of cause in married women is 36 per cent. higher than that for men. The average duration of illness for single women is also in excess of men by 21 per cent. Twenty per cent. of the whole sickness loss is attributed to pregnancy and its associated conditions or complications. In both men and women incapacity for work is relatively most frequent at ages under 20 years. The average duration of certified illness which began and ended was 25·95 days, and this does not cover chronic illness. The illnesses most frequently recorded were of a minor character—e.g., affections of the upper respiratory tract, accidents, and influenza, each of which accounted for 10 per cent. of the total. Inflammatory and suppurative conditions of the skin, gastritis, and bronchitis each accounted for another 5 per cent. of recorded incapacity.

Certain facts emerge from the two reports quoted above. That, with few exceptions, doctors' certification cannot be called to account; that claims for so-called minor ailments cause an average of 25·95 days' incapacity. Doubtless the earlier reference of a number of these cases to the regional medical officer would result in a shortening of duration of incapacity. Possibly a change of definition might assist: "total incapacity" rather than "incapable of work"; but definitions are difficult to render exact and intelligible to those who have to use them. Some blame has been attributed to doctors for certifying too easily, but this has not been proved. The doctor desires to be fair to both sides, patient and funds, and there is quite a large amount of evidence that he has had a great increase in his insurance work, treating a number of minor ailments which were never treated by any doctor prior to inception of national health insurance. As a corollary, if more persons are being treated more certificates will undoubtedly be given for a discovered incapacity for work.

POSSIBLE SOLUTIONS.

Now the day of reckoning has come, and Sir Alfred Watson suggests in the case of insured married women that the weekly rate shall be reduced from 12*s*. to 10*s*. for sickness benefit, and from 7*s*. 6*d*. to 5*s*. for disablement benefit, and even then that an extra halfpenny a week shall be paid by *all* insured women.

Some would suggest instead to take all married women workers out of the national scheme. But this I would deplore, for the central aim of the scheme is to maintain as far as possible the efficiency of the worker by securing early medical treatment, and thus preventing more serious disability. But, alas, the married woman worker has now got to realise that her proved incapacity amounts to too serious a charge on the funds; and that in fairness to the single woman and male worker some plan of collective responsibility must be devised. It would be possible either (1) to increase all women's insurance premiums, or (2) to reduce the benefits of the married. As the married woman secures the greatest percentage from maternity benefit, and a widow's pension (if her husband is insured), she really cannot grumble if her cash benefits are reduced slightly; for her sickness-rate associated with pregnancy lays a heavy charge on the funds.

If later on some of the surpluses of all the approved societies could be secured by way of additional benefit it might be a way to secure the retention of the benefits as paid to-day. But as the Act stands these surpluses belong to individual well-managed societies, and the moneys can only be used in approved benefits for members of those societies. To do other would mean a change in the basis of the scheme whereby the place of the approved societies as the collecting and distributing agencies should be taken by a more central and possibly more bureaucratic method, so that all insured persons secure a share in such additional benefits as are provided by the surpluses.

---

[1] National Health Insurance and Contributory Pensions Bill, 1932. Report by Sir Alfred Watson. H.M. Stationery Office. Cmd. 4073. 2*d*.

My conclusion from this survey is that the National Health Insurance Acts provide a contributory scheme which has to be kept solvent. It is not a charitable fund, and no contributor can expect to get other than fair and equitable treatment. A minority of 1,132,000 married insured women must not be allowed to get more than their fair share of benefits under the present scheme. The unmarried woman will be called upon also to pay an additional halfpenny a week, partly because she also has a higher incapacity than the male worker, and partly because, even though classified as unmarried, she also does cause increase of claims when she herself suffers from diseases associated with pregnancy.

A CONFERENCE ON RADIUM.

THE following account of the origin, conclusions, and outcome of a recent conference on radium has been submitted to us:—

This Conference owed its origin to doubts emphatically and publicly expressed as to whether the policy of the Radium Commission was in certain respects mistaken, and, in particular, whether its decision to convert the existing single unit (in use at the Westminster Hospital) of 4 grammes of radium into four units of 1 gramme each was sound. There were present:—

Lord Dawson of Penn, President of the Royal College of Physicians, in the chair.

Lord Moynihan, President of the Royal College of Surgeons.

Mr. Wilfred Trotter, representing the Medical Research Council.

Sir Frederick Menzies, Chief Medical Officer, L.C.C.

Dr. Watts Eden, President of the Royal Society of Medicine.

Mr. H. S. Souttar, representing the B.M.A.

Prof. Arthur Hall, Mr. Ernest Miles, and Prof. Woodburn Morison, representing the Radium Commission.

The Conference first considered a memorandum, the salient portions of which are as follows:—

> "What this Conference can usefully do is to consider how far the Radium Centres within the purview of the Radium Commission with their equipment, measures, and men and available funds are at the present time suitable places for the use of the 4-gramme bomb.
>
> It is impossible to avoid the conclusion that the benefits from the bomb to patients under conditions existing in the Westminster Hospital have been problematical; that the use of the bomb is at present experimental, involving considerable outlay of money, and that the Westminster Hospital, which exists primarily for treating the sick poor, does not consider it justifiable to employ its funds in the prosecution of this piece of experimental medicine.
>
> When the Conference has heard the evidence on which this conclusion is based it may or may not agree with this conclusion, which would not involve condemnation of bomb therapy as such.
>
> But does it not bring us to this conclusion—namely, that the testing out of new methods of radium therapy, e.g., surface radiation and other similar problems, requires a special institute staffed by skilled radium therapeutists?
>
> England is in serious need at the present time of such a fully equipped radium institute and equally is in need of more skilled radium therapeutists.
>
> At the present time we are at serious disadvantage compared with, for example, Sweden, France, Belgium, &c., each of which countries possesses a radium institute well equipped and staffed. Our present deficiency in men and means is accounted for by the straitened condition of the national finances.
>
> The hospitals of this country are having grave difficulty in maintaining their present standard of work and have no money to institute new services."

The Conference next considered written and oral evidence, and then after full discussion unanimously passed the following resolutions:—

(1) That in view of all the circumstances, this Conference is of opinion that the Radium Commission arrived at a sound conclusion in discontinuing the use of the 4-gramme bomb at the present juncture, though this decision is without prejudice to the question of the therapeutic value of 4-gramme or even larger aggregations of radium.

(2) That in the opinion of this Conference a fully equipped radium institute is needed in London where the more difficult and speculative problems connected with radium and ray therapy can be studied by the combined efforts of a trained staff.

The Conference was in agreement with the Radium Commission that a scientific inquiry on certain aspects of the radium problem would be of value, and after discussion unanimously passed the following resolution:—

(3) That in the opinion of the Conference an expert committee should be appointed with the following references:—

1. What is the scientific case for mass radiation by radium, and what are the advantages and dangers attaching to the use of such radiation?

2. What are the advantages and risks of massive surface radiation by radium compared with those of radium needles and radon seeds?

This committee to obtain any evidence and seek any information which it may think necessary; *its proceedings to be private and its report to be made to the Conference.*

The following is the constitution of this technical committee:—

Lord Dawson of Penn, P.R.C.P.

Lord Moynihan, P.R.C.S.

Chairman.—Mr. Henry Souttar.

Physics.—Lord Rayleigh, F.R.S., Prof. J. C. M'Lennan, F.R.S.

Radiotherapy and Medicine.—Dr. Roy Ward, Radium Institute; Dr. G. F. Stebbing, Lambeth Hospital, L.C.C.; Dr. B. W. Windeyer, Middlesex Hospital.

Surgery.—Mr. Cecil Rowntree, Cancer Hospital; Mr. Geoffrey Keynes, St. Bartholomew's Hospital.

Gynæcology.—Mr. Louis Rivett, Middlesex Hospital; Dr. Elizabeth Hurdon, Marie Curie Hospital.

Experimental Radiation.—Dr. W. Cramer, Imperial Cancer Research Fund Laboratory.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

THE SWEEPSTAKES AND TAXATION.

IT was hardly to be expected that the large sums of money reaching Ireland in connexion with the sweepstakes would not, sooner or later, excite the envy of some Minister for Finance, and, therefore, it was no surprise when the new Minister, who is seeking for money wherever he can get it, and probably in some places where he cannot, announced his intention of making a swoop on the receipts from the sweepstakes. It had been rumoured in advance of the Budget statement that it was proposed to impose a tax of from 5 to 15 per cent., according to different stories, on the gross receipts of the sweepstakes. What is to be done is something different, although the precise procedure is still uncertain. The statement made in the Dáil by the Minister was :—

> "I shall have to turn to the proceeds of the sweepstakes. I have had to consider many proposals in this regard. They were rejected in favour of one which was submitted by the emergency committee of the hospitals, and which outshone all others in its attractive simplicity. I propose to levy 25 per cent. on the hospitals' share of the proceeds of all sweepstakes drawn after March 1st, 1932. This, I hope, will bring in not less than £650,000 this year. In view of this change in the original scheme of the sweepstakes I propose to ask my colleagues on the Executive Council to reconsider the present allocation between public and county hospitals of the proceeds of the sweepstake."

What is not clear is whether the proposed levy is to be a special tax or the ordinary income-tax. The proposal of the committee of the sweepstakes to which the Minister agreed was that the hospital receipts from the sweepstakes should be subjected to the ordinary rate of income-tax. Their reason for this is said to be that they fear that a statement on the face or back of the ticket that the receipts were subject to a special tax would interfere with the sale of tickets. But in the Minister's statement there is no reference to income-tax. Moreover, although the rate of income-tax imposed in the present Budget is 5*s.* in the pound, or 25 per cent., the tax during the last half of the previous financial year, into which the drawing in March falls, was only 3*s.* 6*d.* in the pound. The Minister can hardly intend to make the new tax retrospective, particularly in regard to an income which had been specifically exempted from taxation by previous legislation. There is a good deal of difference of opinion among those interested in the hospitals as to whether a special tax or the ordinary income-tax is the less dangerous method of procedure. While it is recognised that the announcement of a special tax may affect the sale of tickets injuriously, there is a grave objection to establishing the precedent of imposing income-tax on hospital revenues. Hitherto the income of a hospital as a public charity has been exempt from income-tax, and it is feared that a future Minister may regard as a precedent for taxation of the ordinary income of a hospital the taxation now to be imposed on income from a special source.

THE BUDGET AND MEDICINE.

Apart from the tax now to be imposed on the sweepstakes' funds the new Budget touches in other respects on the interests of the public health and on the working of the medical profession. It is proposed to make a sum of £5,000,000 available for building. On the other hand, however, the costs of building are likely to be greatly increased by the new duties which will press specially heavily on builders' materials. Again, a sum of £100,000 is to be provided for the supply of milk to poor children. The application of the entertainments tax to physical exercises, games, and athletic sports will interfere with the pursuit of these means to health and physical efficiency. Some years ago the legislature recognised the educational and hygienic value of open-air sports, and exempted them from the entertainment tax. The fresh imposition of it is a retrograde step. One of the new duties—the "package tax," a tax of 2*d.* on every parcel or packet or bottle ready for sale which enters the country—is likely to cause grave inconvenience in medical practice. The Minister states that his object in imposing this tax is, in the first instance, to raise revenue, and, in the second, to increase employment by causing the packing or parcelling to be done in the Irish Free State. He overlooks that the label on a closed packet or bottle is a guarantee that the article is the product of a particular maker. In future, the purchaser must either forego this guarantee or pay 2*d.* for it each time. The tax will certainly increase the price of proprietary preparations appreciably.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

UNQUALIFIED PRACTICE IN HUNGARY.

In the present depressing conditions it is not to be wondered at that the profession is eager to track out all factors that may damage medical practice. The Hungarian law prohibits unqualified individuals from treating patients for gain, and from carrying on such practice as a breadwinning occupation. This definition is not satisfactory, for unqualified persons can evade it by engaging qualified physicians to work with them, or by other means. The Minister of Public Welfare, in view of the great increase in unqualified practice, has recently asked that the law should be tightened up, and that offences against it should be dealt with in the higher courts instead of, as now, by magistrates. The Minister of Justice did not make this change, but he has instructed magistrates to deal more severely with proved cases of overt breach of the law. A more difficult problem is that of the pharmacist-prescriber. Pharmacists are entitled to make up compounds according to medical prescriptions, and to sell drugs asked for by customers by name—for instance, aspirin, camphor liniment, or tincture of iodine. But if a customer asks for "something for" headache, or heartburn, or pain in the back, and the chemist sells him pyramidon, milk of magnesia, with perhaps the addition of belladonna, he commits an offence. A pharmacist must not explain the directions given on the use of drugs, and still less may he answer questions put by customers on the kind of life they ought to lead when taking certain drugs. If this enactment were strictly applied, hardly a single chemist would escape punishment. The medical profession tacitly acknowledges that right of the public to buy household remedies from the chemist, without consulting doctors. But it raises objections against the practice which nowadays is quite common whereby a patient actually consults the chemist and takes his advice and medicine. A chemist may prescribe and dispense, say tinct. opii, for a patient who comes complaining of abdominal pain ; if the drops do not cure the pain the chemist suggests some narcotic tablets. This is the sort of case in which the doctor may be called in at a late stage to establish a diagnosis of perforated appendicitis. The chemist who is reported for prescribing remedies for gonorrhœa, chronic eczema, varicose ulcers, and hæmorrhoids, is fined so little if the charge is proved that it pays him to continue this practice. The Society of Physicians of Leopold City, a district of Budapest, have brought up the matter, with some notable examples, in the hope that action will be taken in the matter.

THE INFLUENZA EPIDEMIC.

This year the influenza epidemic presented itself considerably later than in former years. While its usual advent in Hungary falls in the second half of January, this year it appeared in the second third of February. The epidemic was unusually widespread, the number of cases being very large, particularly in late February and early March. In some houses almost all members of the family contracted the disease. Schools and some offices had to be closed. The Budapest Court could not hold sessions because three-fourths of the judges were in bed. Fortunately the majority of cases were mild, and passed off without serious complications. Of the latter, bronchitis and indigestion were most frequent. The mortality was fairly low. In Budapest, at the height of the epidemic, there were on an average two fatalities daily, mostly due to pneumonia. The epidemic lasted up to the end of March.

MEDICINE AND THE LAW.

"Osteopathic Physician and Surgeon."

THE broad effect of Section 40 of the Medical Act is to forbid an unregistered practitioner to call himself a physician or surgeon. The Act, be it never forgotten, was passed with the express object that persons requiring medical aid "should be enabled to distinguish qualified from unqualified practitioners." Somehow an idea has gained currency that the words physician and surgeon may safely be used by an unregistered person if only they are embroidered in their context, and that, for instance, the adjectival description "osteopathic physician and surgeon" may be assumed with impunity. The belief seems to be attributable to the early decision in Ladd *v.* Gould, a case in which a dentist had described himself as a "surgeon and mechanical dentist." The magistrates then came to the benevolent conclusion that the word "surgeon" was merely used to indicate what branches of dentistry the defendant carried on, and not to represent him as a surgeon within the Medical Act. The result of this somewhat curious finding of fact was that the High Court ruled that the defendant had not unlawfully taken the title of surgeon. The case was decided in 1860, only two years after the Medical Act had been passed; it depended upon the special facts found and its authority is now doubtful.

In an important decision on May 11th the High Court has ruled that the name-plate of an unregistered practitioner which bore the words "Prof. A. E. Shakesby, D.O. (Lond.), Bonesetter, Osteopathic Physician and Surgeon," is an infringement of Section 40 and justifies a conviction. The Marylebone Police-court magistrate found that Mr. Shakesby was not registered under the Medical Act; he was not a legally qualified medical practitioner within the statutory meaning. He described himself as a doctor of osteopathy and an honorary member of the Incorporated Association of Osteopaths, Ltd. He held a certificate issued by the Association, but the court had no evidence of what examinations had to be passed before the certificate could be awarded. The Association issues a directory which contained the statement "Each member has a right under the articles of association to the title of osteopathic physician and surgeon." It would be strange if the Association could by such a statement repeal Section 40 of the Medical Act, but the significance of the statement is that Section 40 contains the words "wilfully and falsely," and that Mr. Shakesby, having been thus assured by the statement, might honestly believe he was entitled to describe himself as he did. These words "wilfully and falsely" (which the equivalent statutory provisions relating to registered dentists and veterinary surgeons manage to do without) are an element of the offence under Section 40. It was argued for Mr. Shakesby that he was entitled to describe himself as a bonesetter and to amplify that description by adding "osteopathic physician and surgeon"; the words "bonesetter" and "osteopathic," it was said, so qualified the description "physician and surgeon" as not to imply that Mr. Shakesby was registered under the Act. If he honestly believed he could so describe himself, he had not taken the description "wilfully and falsely," even if his belief was wrong. The magistrate held that the titles had been used "wilfully" but in view of the qualifying and amplifying words in the context, not "falsely." This meant that the offence had not been established in all its ingredients; the informations against Mr. Shakesby were therefore dismissed. On appeal the magistrate was held to have been wrong. The King's Bench Division has remitted the case to him with a direction to convict. Dealing with the argument about qualifying and amplifying words, the Lord Chief Justice observed that Mr. Shakesby's counsel seemed to be urging two contradictory things. He had argued that the words "physician and surgeon" could be ignored as mere surplusage; simultaneously he was suggesting that the words were used because they were "something grander" than the word "bonesetter." Then, by asking one penetrating question and answering it himself, Lord Hewart put the case for us in a nutshell. Why were "physician and surgeon" something grander? Because they appeared to suggest that Mr. Shakesby had qualifications which in fact he had not and which the Medical Act forbade him to assume.

The High Court decision, it will be noticed, moves in the direction of an absolute prohibition against the use of the descriptions "physician" and "surgeon" by an unregistered practitioner. Was not this the intention of the Medical Act as expressed in its preamble?

Pay-beds at the Miller General Hospital.

A year ago Mr. Justice Farwell made an order that the Miller General Hospital for South-East London might for twelve months appropriate 20 beds to paying patients. As explained at the time, the original constitution of the hospital made no provision for paying patients; the hospital is dependent almost entirely upon subscriptions, donations, and legacies which nowadays are a somewhat precarious source of income. The twelve months having elapsed, fresh application was made to the Court. Mr. Justice Farwell renewed the order, with minor modifications, till May 15th, 1937. The maximum number of pay-beds remains at 20 under the new order; these may be in any part of the hospital and may include all or any of the eight beds in private rooms; as far as possible, the private patients in cubicles in the wards are to be kept together in adjoining cubicles; the board may use any private room for a paying patient if in the opinion of the medical or surgical authorities the room is not required for a non-paying patient owing to his condition. The charge for the pay-beds is not to exceed seven guineas a week.

PANEL AND CONTRACT PRACTICE

NATIONAL HEALTH INSURANCE BILL.

The Minister's Introduction.

ON Wednesday of last week in the House of Commons Sir E. HILTON YOUNG (Minister of Health) moved the second reading of the National Health Insurance and Contributory Pensions Bill, designed, he said, to ensure the financial stability of a scheme which had for 20 years become increasingly interwoven with the social structure of the country. Under it there were 17 million insured persons who contributed year by year no less a sum than 26 million pounds. The Exchequer contribution, the sum which the nation paid in to the assistance of the scheme, was 6½ million pounds a year. In the course of the last 20 years no less than 434 million pounds had been expended in benefits. The organisation by which the scheme was administered was in the hands of 7600 approved societies and branches of societies.

FOREWARNINGS OF DISASTER.

For the first 10 to 15 years the finances saw nothing but prosperity. Large surpluses were earned, and in consequence large additional benefits could be paid—no less than 21 million pounds in the last ten years; and owing to those earlier years of prosperity, very large reserves had been accumulated by the societies—no less than 117 million pounds. For the greater part those reserves were earmarked against the positive actuarial liabilities of the societies, so that not the whole of that 117 million pounds was free for additional benefits. With the change which had unfortunately come about in the circumstances of the nation came a change in the circumstances of the scheme. A threat to the absolute stability of the finances of the scheme was foreshadowed some years ago. About two years ago his predecessor called for a special report. In that report they saw the first foreshadowing of what was beginning to be threatening in the circumstances of the scheme, because the principal circumstance that that report brought out was a very startling increase in the sickness experience of married women, which in the years 1921 to 1927 had increased, as regards sickness benefit, by no less than 106 per cent. above expectation, and, as regards disablement benefit, by no less than 159 per cent. above expectation.

In consequence of this warning, the Minister of Health issued a circular, in 1931, in which he sought the following remedies—*namely*, a more careful supervision of claims made and *better* medical certification in respect of the claims: in other words, a closer scrutiny of claims made against the insurance fund. Unfortunately, those remedies proved neither sufficiently deep nor wide enough to meet the case, and, *after that forewarning, there came the* severity of depression, and, with the severity of depression in the country as a whole, it became obvious that something was seriously amiss with the finances of national health insurance. Things were beginning to be unduly unfavourable on both sides of the account. Claims were increasing, and particularly in respect of the women's claims, more especially married women. On the other side of the account—the contribution income—a new menace *appeared. This* second menace was entirely due to the growth of unemployment. Contributors were constantly falling into arrears with their contributions, and the income from contributions was consequently falling off.

GOVERNMENT ACTUARY'S REPORT.

After those forewarnings at the beginning of this year the blow fell in the form of the actuary's report upon the scheme for the third valuation period. The situation it revealed was this: the valuation showed that they had arrived at a point at which the health insurance scheme was living upon its accumulations. During the period from the first to the second valuation, that was, during the period of prosperity, the surplus assets of the approved societies grew by no less than 25 million pounds. During the period of the second to the third valuation the surplus had increased by 12½ million pounds only, that was, half the previous increase, and, what was more unfortunate, that increase was an illusory one, because it was due, as to about half, to interest upon funds previously accumulated, upon which they must now be drawing, and as to the second part of it, to non-recurring margins. The increase of surplus assets at the last period was, therefore, illusory, and as things stood at present the rate of increase in the surplus assets of the approved societies and of the scheme as a whole was, in substance, nil. They had arrived, therefore, at a point at which, without an increase of surplus assets, the future held nothing but the necessity of living upon accumulations.

That state of affairs found its expression, of course, in the reaction upon the additional benefits. After the second valuation no less than 95 per cent. of the approved societies could, and did, give additional benefits. After the third valuation additional benefits had had to be reduced for *6¼ millions out of 17 millions*, and, *more unfortunately still*, in respect of no less than 4¼ million contributors the additional benefits had had *to be discontinued altogether*. The most menacing feature of all was that no fewer than 418 *societies and branches found themselves* not only in a position not to give additional benefits, but actually with a deficiency; that was if they did not fall back upon central aid they would not be in a position to pay the very *minimum of statutory benefits* which the scheme required. The Government actuary in reporting on the state of affairs said: "*Existing* surpluses provide only a temporary bulwark, and serious deficiencies are in prospect."

THE THREAT OF BREAKDOWN.

If, said Sir Hilton, they went on as they were going with *National Health* Insurance, at the end of the next valuation period there would be widespread deficiencies among the approved societies. They would be unable to pay the statutory benefits which the scheme required. The deficiencies would be so great that the resources of the scheme would be unable to meet them, the scheme would be insolvent and would break down. This scheme had been, in a way, the pride of our social organisation, and we had boasted of its financial aspects as an example to the world. Prompt action was absolutely necessary, and it must be based upon two principles. First of all, they must secure the solvency of the scheme. In the second place, they must maintain the other foundation-stone of the scheme, which was that it was a contributory scheme—a scheme based upon the principle that people got what they paid for. It was that contributory element which they should look upon as having to be absolutely preserved and fortified in anything that was done.

The *first* cause of the threatened breakdown was the increase in the sickness experience, and that was particularly the case in regard to the women's claims, and more especially in respect of the married women. During the last valuation period the sickness and disablement benefit paid to women was nearly 4 *million* pounds in excess of the actuarial provision; that was after every allowance had been made for a reasonable increase to be normally expected it was found that the claims for women during the period was 4 million pounds in excess of the expectation. The excess was greatest at the end of *the period*—the last year of the valuation. The report by the Government actuary showed that during the years 1928–30, after the valuation, the average *expenditure on* sickness and disablement benefits of women exclusive of the State grant exceeded the provision made for it by no less than £850,000 a year. *This* increase over expectation had got worse and worse. *The* average yearly loss per head on married women was 3½ times greater than it was with respect to *unmarried* women.

Only two things could be done. They must either increase the contributions or decrease the benefits. In *order* to make both ends meet by raising the contributions they would have to increase them for all women from 8½*d.* to 10*d.* The result of that would be that they would have to make the woman's contribution to the scheme higher than the man's contribution. With the increase of contributions for unemployment and pensions there was the strongest possible reason against making further increases in contributions for national health insurance; and, when they looked round at the general conditions of the nation and at the industrial depression, and considered the remedies which were appropriate for our national disorder, the House would come to the conclusion that it was frankly impossible to place any fresh burden in the form of increased contributions upon either the employer or the employed. (Cheers.)

PROPOSED DECREASES.

The House was already acquainted from the White Paper with the nature of the decreases which he proposed. There were one or two points that deserved special consideration. Discrimination was made between married and unmarried women. It would be unfair to call upon unmarried women to bear the burden incurred owing to the increase of claims by married women. The unmarried women in the scheme were to married women as four to one. There was, too, a difference between the economic position of the married woman and that of the unmarried woman. Even after the reductions in benefits they would still be above the pre-war level, and would still be substantial benefits. As a result of this adjustment they would return to what he thought was a due proportion between sickness benefit and disablement benefit, the benefit which followed after the first period of sickness was over. It was always looked upon as a good rule that disablement benefit should be half sickness benefit, and they were now re-establishing that just proportion. Undoubtedly the benefits were not as great as they had been, or as they would like them to be, but what was the intention of national health insurance? After all, it was only to provide an assured minimum; it made no pretence of being able to provide maintenance. By the adjustments which he proposed, not a single penny was taken from the fund. All the money that was there before was still there; it was simply a matter of adjustment to make sure that the money went round and that the scheme did not break down.

There was another menace to the scheme on the other side of the account which was wrapped up with the question of arrears. The cause of the difficulty was the system established in 1928. That system turned out to be too big a burden for the finances of the scheme to bear. The system was that all arrears of contribution because of unemployment were totally excused. The burden that was thrown upon the funds of the societies in the then state of unemployment was £700,000 a year. Of that £500,000 was met out of the central fund by an adjustment of the unclaimed stamps account. Only £200,000 was thrown upon the finances of the approved societies. But with unemployment in its present condition of severity the burden which this method of excusing all arrears threw upon the finances of the fund was 2½ million pounds a year. Of that, 2 million pounds had to be borne by the societies, and the funds available from the unclaimed stamps account were failing. That burden of 2 million pounds upon the funds of the societies was too heavy to be borne, and the societies could not continue it without being driven down into deficiencies, and practically into insolvency. It was urgently necessary that an intervention should be made in order to relieve them from this burden, which had proved intolerable.

The proposal was that arrears due to unemployment should be excused to the extent of one-half, the remaining one-half, less an allowance of two contributions, to be met by the insured person if he wished to cover himself for full benefits. This proposal would result in a scheme of arrears very much as before 1928. Arrears were to be excused in any case during the weeks of notified incapacity. Powers were taken to ensure that, if there was any improvement in the unemployment position, more generous treatment could be given by the excusal of more than one-half of the arrears due to unemployment. In approaching this question he had tried to do what was necessary to make things safe, but not to do anything more than was necessary in the hope of things improving, and to take power to put things back into a better state of affairs than they were before if and when the general finances of the scheme enabled him to do so. The result of the scheme with regard to arrears was that it would reduce the burden on societies by one-half, that was by 1 million pounds a year; 1 million pounds a year would still be borne by the societies, and the other million pounds would fall upon the contributors. This scheme had been submitted to the Consultative Council, and they agreed that it was the legitimate and right way of dealing with the matter.

DRAWING ON THE CENTRAL RESERVE FUND.

There was a further protection which he proposed to give to the finances of the approved societies. It was not right that, owing to this burden of arrears due to unemployment, the finances of any society should be driven into a deficiency. He therefore proposed that, if any society found itself in danger of a deficiency, owing to the burden due to arrears, it should receive a grant of the balance necessary to avoid a deficiency from the central reserve fund, and it should receive that grant in priority to any claim upon its reserves. The consequence of that would be to spread the burden of avoiding deficiencies due to arrears over the central finances of the scheme. These two proposals in respect of benefits and contributions did not wholly satisfy the actuarial demands. He had not gone so far as the most rigid standard of actuarial requirements went, but he was entitled, as hon. Members would see by reference to the report of the Government actuary, to count on an improvement in respect of claims owing to that improvement in administration which was inaugurated by Mr. Greenwood when he was Minister of Health. He (Sir Hilton) was told that it was not unreasonable to count on an improvement of 10 per cent. in respect of claims owing to the improvement in administration. If that were so, they would, by these two measures, as far as it was reasonable to foresee, assure the financial solvency of the finances of the health insurance scheme. He did not mean to say that there was not an element of uncertainty. He had felt it right in the present condition of the nation's finances to stretch a point and to take a risk, so long as it was not an unreasonable risk, while avoiding going further at the moment than was necessary for the recovery of the general prosperity of the nation.

PROLONGATION IN INSURANCE.

At the end of his speech Sir Hilton Young turned to the question of prolongation in insurance of the unemployed who, because of the failure of their contributions, would otherwise go out of insurance altogether, losing all their insurance rights, their rights to sickness benefit, medical benefit, and lastly, and worst, losing their rights to the widows' and old-age pensions at 65. Unless something was done some 80,000 men and women would pass completely out of insurance owing to unemployment. The general effect of his proposal would be that under the national health insurance scheme every unemployed man and woman would have five and a half years' free insurance without contribution, and for pensions' insurance the average unemployed man or woman would have ten years' insurance for only two and a half years' contributions. At the end of this period of prolongation they would revert to the present system of an average of 21 months' free insurance for all persons after their contributions ceased, and, on the top of that, one year of free insurance. There was one other proposed alteration great importance. At present, after a man arrived the age of 60. he was continued in insurance, hether employed or not, until the age of 65 in order qualify for the old-age pension. It had been found at an extension of that privilege could be given by ducing the age of 60 to 58½. This and other ovisions of this Bill, Sir Hilton said, had the support d approval of the approved societies.

Motion for Rejection.

Mr. RHYS DAVIES moved the rejection of the Bill. le said that he agreed that they must secure the lvency of the scheme, and he thought that there as no section of the community that was not anxious see the scheme based on insurance and actuarial rinciples. But if the original contracts had been arried out by the State, and the usual subsidy to hese funds had been continued, the surplus of the hird valuation would have been equal to that on the econd. In spite of all that had been said about he scheme it was still as it stood the safest and oundest social insurance scheme in the world. Had t not been for the fact that the Ministry induced nost of the approved societies to separate for valuaion purposes the funds of the men from those of the vomen he was positive that those societies would iever have had reason to complain of the heavy laims of married women. The problem would never have arisen in such an acute form. He was quite sincere in his opinion that the Ministry of Health could on the financial points of this Bill have found a way of doing all that they desired in respect of the married women without reducing their benefits.

ALLEGED LOOSE CERTIFICATION.

A large proportion of the increase in the sickness claims of married women, said Mr. Davies, came from the loose certification of the panel practitioners. The number of medical men in this country was, he believed, growing in proportion to the number of the population. He did not dispute that the doctors must have a livelihood, but the medical practitioner to-day was not adopting the same attitude towards panel practice as he used to adopt when he was employed by the old friendly societies. If the panel practitioner of 1932 did his work as conscientiously as his predecessors did for the friendly societies 20 years ago the House would not be faced with the problem of married women's claims to-day. The Ministry of Health had been so dissatisfied with some panel practitioners that they had set up what was called a regional medical service which took an oversight over the work of the panel practitioner. Approved societies that were dissatisfied with the certification of the ordinary panel practitioner sent thousands of cases annually for second medical opinion. Were it not for the work of the regional medical officer, the percentage of this increase might easily reach double what it was now. The Ministry of Health had done a great deal in regard to this problem. They knew as well as the administrators of the approved societies that the situation regarding certification was very unsatisfactory. In his view the medical practitioners who were dealing with national health insurance ought to be employed by the State. He saw no other way to secure proper certification.

Mr. McGOVERN: Is the hon. Member suggesting that the medical profession are passing people for benefit who are not suffering from illness?

Mr. DAVIES: The real fact is that the average panel doctor is doing his work well, but there are certain practitioners who are known to be granting medical certificates improperly.

Mr. MAXTON: What is the motive?

Mr. HOWARD said that if they did away with the opportunity which was allowed to patients to transfer from one practitioner to another they would prevent the granting of these easy certificates.

Mr. DAVIES said that that was exactly his point. This problem of the medical profession was not a new one. Those who administered the scheme knew too of the extravagant claims of some dentists, opticians, and surgical instrument makers. He believed that by adopting a better system of administration, by securing better medical certification, and by the elimination of what he termed uninsurable types of cases from the scheme, it would still be possible to save the married women and the single women from any reduction of benefits.

A SPECIAL CLASS FOR MARRIED WOMEN.

Mr. LLEWELLYN-JONES said that some of those who were associated with the administration of national health insurance felt that this Bill did not go far enough, and that the whole position would not be safeguarded by this measure. Therefore on the committee stage it was proposed to put down an amendment which contemplated that all married women should automatically be transferred to a special class as from the date of marriage and become entitled to the benefits of that class, whether or not they continued in employment; and that those who ceased employment would ultimately pass out of insurance in the same manner as at present; whereas those who continued in employment would requalify for full insurance by shorter waiting periods than at present. He was satisfied, however, that legislation alone was not going to clear up the grievances of which they had to complain. Very strong stern administrative action would be required.

He disagreed with the attack which had been made on the panel practitioners by Mr. Rhys Davies. For over 20 years he had sat as chairman of the Insurance Committee for his county of Flint, and he could not remember a single case of a complaint by an approved society against a medical man in his county as regarded irregular certification. On the whole he believed that the great mass of medical practitioners on the panel endeavoured to administer the Act in the most straightforward manner in the interests of their patients.

Mr. DAVIES said that that was exactly what he had said, but he pointed out that if 2 per cent. did not do the right thing it was damaging to the funds of the societies.

Mr. LLEWELLYN-JONES said that he could not agree with the line which his hon. friend had taken. He had made a very bitter attack upon the medical profession. He was quite sure that if complaints about improper certification by doctors were reported to the British Medical Association immediate action would be taken. But he (Mr. Llewellyn-Jones) did not wish it to be understood that he thought that the medical profession could not have done more than they had done in the matter of certification. It was a very easy thing for a medical man to err on the wrong side. The difficulty of the medical man was very much greater in the case of women, particularly of married women, than in the case of the ordinary worker.

REMEDIES.

During the past few months, Mr. Llewellyn-Jones continued, an attempt had been made by insurance committees with the concurrence of the Ministry of Health to arrange for conferences of medical men, representatives of insurance committees and of friendly societies, and he was satisfied that those conferences had resulted in a vast amount of good. In regard to the question of certification and excessive claims on societies, he was not satisfied that societies had done all that they could. He thought that the system of sick visiting was of very little value. It was only by constant vigilance that they could get off the books of the approved societies persons who were malingering.

Mr. MELLER said he had spoken in the past with regard to medical men and health insurance, but he was not prepared to say that bad medical service was so widespread as to make the difference between the expected sickness experience and the actual.

In the main he believed that the doctors rendered excellent service. It was a matter for coöperation between all parties concerned in this question of health insurance. A deputation representing all types of approved societies had waited on the Minister and had expressed their firm conviction that the present position of affairs must be met in the way the Minister of Health had met it. He hoped that the Minister, having taken the advice which was tendered to him in the interests of the societies and of the insured persons, would also take the advice which would be tendered to him in the form of a new clause which would be submitted in Committee to extend the differentiation between married women and single women. Otherwise he agreed with the main principles of the Bill.

THE PRINCIPLE OF EQUALITY.

Miss **RATHBONE** asked the Minister whether the method adopted in the Bill was the only possible means of meeting the deficiency. Might it not be possible to meet it by some form of pooling the surpluses of those societies, a very substantial number, which still had such large disposable surpluses that they were able to give substantial additional benefits. Was it not right that in a State system of insurance, contributed to by the State, the principle of equality should be carried at least far enough to assure that the rates of benefit necessary for subsistence should be paid to everybody before any group of fortunate contributors were allowed to enjoy additional benefits ? She did not think that it was beyond the power of the Minister of Health to devise such a method if he wished to do so. She would have no hesitation in opposing the Bill as long as it remained in its present form.

SOLVENCY OR HEALTH ?

Mr. **MAXTON**, in supporting the motion for the rejection of the Bill, asked if the Minister of Health ought to allow the question of the solvency of the fund to take first importance in his mind. The main purpose of the national health insurance scheme was the maintenance of the general health of the community. One of the most obstinate problems was that of the maternal death-rate in childbirth, and he urged the Minister to bear that matter in mind when he picked out the married women as the special instrument for achieving a solvent balance-sheet. He asked the right hon. gentleman if it was sound national economy to risk a serious deterioration in the health of the nation. The Government were asking the sick women to shoulder an added burden to save the nation from collapse.

A SCOTTISH SCHEME.

Mr. **SKELTON** (Under Secretary of State for Scotland) said that the Bill would, to a considerable extent, solve the problem of arrears which had pressed so heavily on the Scottish friendly societies. The Scottish Department had attempted to solve the problem of the increase in the claims of married women. Their report would show what had happened since June, 1930, in relation to sickness and insured persons in Scotland, and the report would tabulate the number of certificates given by medical men. That would furnish a double check on how far in certain districts certain complaints and ailments were prevalent, and the kind of proportions in which medical men gave certificates. That would furnish a very real addition to their knowledge of the question of insurance medical benefit. The first report, for the year from July 1st, 1930, to June 30th, 1931, would be published shortly.

THE MEDICAL VIEW.

Lieut.-Colonel **FREMANTLE** said that he was much interested in the scheme which had just been propounded by the Under Secretary for Scotland—a kind of sleuth-hound, Sherlock Holmes scheme for the investigation of the crimes or otherwise of the medical profession in this matter. Of all those who were concerned with the question of the health of the people generally, none would wish more strongly than the medical men themselves that this inquiry should be successful in running down any real negligence on the part of the panel practitioner. No one could be a friend of the medical profession, or of the panel practitioner in particular, who in any way supported any suggestion of laxity on their part. It was true that a panel doctor often knew, while the regional medical officer who came in from outside did not know, the real human side of a case, and that had to be considered in regard to the difficulty about certification. If these matters were to be judged by bureaucratic methods, and if one doctor who certified 50 per cent. more patients than another was to be adjudged wrong, it would reduce the whole thing to ridicule.

They could not, he went on, judge human action by percentages. Material facts could perhaps be so judged but they were dealing in this instance, not with material facts, but with human judgment, and that was the difficulty of getting at the real truth on the subject of certification He agreed that the difference in certification for sickness benefit could not all be attributed to malingering, but that, nevertheless, some must be attributed to it. He did not like the use of the word "malingering" or the phrase "false certification," because such words led them astray. The great majority of people did not deliberately break the law or cheat, but they were human, and the result was that, on the one hand, they naturally took benefits as they came to them in the ordinary kind of way, while, on the other hand, the doctor signed certificates as a matter of course, not meaning to deceive anyone or to betray anything, but in the hurry of his ordinary practice. The medical profession were probably the most unbusinesslike people in the world in their general practice, because their work had a compelling human appeal that they could not be businesslike in their ordinary arrangements. Even when doctors had time to be businesslike, they suffered from never having learned the habit of being businesslike. It was natural for them to do what they could for their patients, and to do what their patients wished them to do; and it was natural that if the patient came to his doctor and said, "Sign me again, doctor," he signed. He (Colonel Fremantle) agreed that the doctor was not fulfilling his contract under the insurance system, and that an insurance system would break down if that practice were followed generally. He was only saying that it was a natural tendency, and the reason why it involved going against the rules was that the whole national health insurance system was against the rules. When they had anything systematised they were bound to have difficulties.

SOUNDNESS OF THE SCHEME : SIGNS OF IMPROVEMENT

They had to keep the insurance system watertight and financially sound if it was not to break down, and to see that the systems of public health and public assistance should be improved wherever possible. The question, said Dr. Fremantle, was in what way they could make it sound. The figures showed an increase in certification up to 1927, but he was rather surprised that the Minister had not also remarked that the figures since then showed a definite improvement. He rather left the impression that there had been this constant increase in certification for sickness and disablement benefit among women.

As a matter of fact, in the last three years there had been a considerable improvement. Disablement and sickness were practically stationary at a level slightly above that reached in 1927 for unmarried women, while those for married women had substantially increased. The Minister was banking on having a 10 per cent. improvement during the next few years. The figures for the last three years of the Hearts of Oak Society, with which he was proud to be sociated in the work of honorary arbitrator, certainly d not show that there was likely to be a 10 per cent. iprovement. There had been an improvement on some rs, but on others it was very slight. The figures for omen's sickness in 1930 were £70 benefit per 100 members, id in 1931 £60. Disablement benefit was reduced for all omen from £52 to £49, with different figures for spinsters opposed to married women. Married women were very uch more. There was not very much reduction, and that duction really corresponded to the reduction in the scale benefits.

He was afraid that the 10 per cent. reduction on which ese estimates were framed would not be sufficient, and at was why he hoped they might be able to get support r the amendment which had been adumbrated by Mr. l-wellyn-Jones. It was a natural, reasonable, and right iggestion, in accordance with the hon. Member's diagnosis the trouble. Women, when they were married, tried, herever they could, to retain benefit so long as they mained in the same class. The suggestion in the amendment was that they should go into a separate class—lass K—until they were definitely disabled, and then they ould go back to Class E and get their benefit. That was human, natural way of meeting the point, and they would et by it a further reduction in sickness and disablement ithout any real hardship.

PROLONGATION OF BENEFIT.

Dr. Fremantle said he had been asked also to upport an amendment put forward by the National ssociation of Insurance Committees to prolong nedical benefit along with the prolongation of pension ights. Obviously they would all wish to see that f possible, but it depended on finance. He undertood from his society that it would not be practicable o make that further concession of medical benefit or another two years, but he hoped that the matter would be properly looked into, and that they would consider it in committee. If in any sense the Bill reduced benefits it must be an unpopular thing to do, but if it was right they ought not to hesitate. They would gain credit and confidence for the National Government if they helped to make the scheme sound. So much depended on this because the health of the people depended on it. The whole system was badly conceived and largely politically conceived, and there was a great deal wrong in it. It was more directed to benefit than to treatment and prevention of sickness. It had failed a great deal from that point of view, but they had to make the most of it, and they had made a great deal of it. There was a great deal of good in it which could be preserved and enlarged. It was not true that the health of the people was deteriorating. It was extraordinary how the health of the people had been improving in spite of all the difficulties of the past few years, and they had to see that that improvement and the benefits continued. They could only do so if sound financial lines were adhered to.

A QUESTION OF COMPLAISANCE.

Sir H. CAUTLEY asked if there was any information in the possession of the Ministry of Health showing the effect of paying benefit for the first three days. One heard rumours and stories of how members of approved societies in town wished to take a holiday, a long week-end of four or five days, and that a complaisant doctor did not take very much trouble, and the members went on benefit for those week-ends. He wondered whether that benefit, which he had always mistrusted, had not been abused and if there had not been laxity in this administration.

Dr. O'DONOVAN said that this was a matter of interest to the medical profession. He asked Sir H. Cautley to translate the stories of what he heard into how he heard them and from whom. The medical profession, he said, would then be greatly obliged to the hon. Member.

Sir H. CAUTLEY said that he only heard it. Numbers of people told him so, but otherwise he was not prepared to justify it. He was asking for information, and whether there were any statistics on the subject. He also asked if it would not be advisable to alter the system of the relationship of the panel doctor and his insured patients. At present no notice had to be given of any change of doctor. Could a doctor be more secured in his position by two, three, or four months' notice being required from a patient before he could change his doctor? At present the doctor was put in the position that if he refused to sign a certificate that a panel patient was ill, the patient might, in the heat of the moment, apply for a change in his medical attendant. While he did not suggest that the doctor did not try to do his best in a very difficult situation, he said that it was not fair to him, and that he ought not to be placed in that position.

A DEGRADING POSITION.

Mr. MACQUISTEN said that there was no more unpopular Act amongst the masses of the people than the National Health Insurance Act. The vast mass of doctors had been reduced from a profession to becoming tax collectors, a brotherhood of Zaccheus. They did nothing but collect and fill up forms and were insulted by committees of laymen, and surcharged if they gave patients medicines which were a little expensive. The medical profession had been largely degraded by the position into which its members had been put by this abominable Act. *A different breed of men had come into the profession*, and doctors themselves, or most of them, would tell them how they detested it.

A doctor friend of his in Edinburgh told him that he was getting £1500 a year for a few working men waiting in his consulting room in the evenings. He said that he got £75 a quarter from people who were too indignant to nominate a doctor and whom he therefore did not attend, and he felt as if he were getting money under false pretences. He (Mr. Macquisten) asked why he did not "chuck it," and his reply was that if he did so some other fellow would get it; that it helped to pay for his car and household expenses, and enabled him to build up a West End practice on the backs of the poor. It was all nonsense to talk about the Act protecting the people's health. Dr. O'Donovan had asked Sir H. Cautley to give instances in regard to his references to the medical profession. He (Mr. Macquisten) would give instances. To begin with, a substantial percentage of doctors practically wiped their boots on the panel patients when it was impossible for the patient to change his doctor. When the patients got some liberty and the chance of changing their doctor, there was the inevitable result of competition for patients. He did not blame the doctors. They were only human beings, and if he were put in the position of having to compete with other doctors to get 10*s.* a year each from several thousand people he would naturally look after himself, though he might curse the Government which had put him in that position.

LAX CERTIFICATION.

Mr. A. GREENWOOD said that it was difficult to ascribe reasons for the increase in the claims among married women, but he was satisfied that the long drawn out trade depression was one of the most important. While he did not suggest that the doctors were acting dishonestly or that married women were trying improperly to obtain benefits under the National Health Insurance scheme, it was undoubtedly true that there were cases of lax certification by doctors and a desire on the part of insured persons to get something to which they were not entitled. It was not fair to reduce the disablement benefit of the single women. If the nation were really hard pressed he would not complain of a reduction of benefits all round, but the trouble was that they were not all poor together, and it was a little mean to filch half-a-crown from the pockets of married women, honest industrial workers, in a time of sickness.

The Parliamentary Secretary Intervenes.

Mr. ERNEST BROWN (Parliamentary Secretary to the Ministry of Health) said that solvency was not an abstraction but an essential condition of paying not only the proposed benefits, but any benefits at all. In making the proposed changes the Government had had to do it so as best to guard the pension rights of these poor people as far as possible, consistently with a sound scheme. Colonel Fremantle and other Members had raised the question of a special class for married women. That was a case which could be presented during the Committee stage of the Bill, when everything for and against the proposal would be heard with great care by the Minister of Health. Everyone knew that the most subtle and difficult of all approved societies' problems was the decision as to when a married woman was or was not sick. It was not only a difficulty for the doctor, but for the approved society. Even in the smaller towns, where everyone's movements were known, it was very difficult to decide whether there was laxity or not in regard to certification of married women. It was certain that the actuarial risk in the case of married women under an insurance scheme was out of all proportion to the risk in the case of men or of single women. Because that risk had assumed such great proportions, the Minister of Health had felt it right to face the problem in the way which he had done, and to say, regretfully, that the only thing to be done was to tackle the question of what was the risk, in terms of the solvency of the scheme, in the case of married women.

AN ANTIDOTE.

Dr. O'DONOVAN said he had heard a most corrosive contribution to the debate, and if taken seriously it might lead administrators into difficulties and politicians into trouble, and lead to the use of the medical profession as the goat of Israel, so that they might tie their sires upon its horns and push it into the wilderness. They had heard from Mr. Macquisten that doctors accepted their money as if that money were obtained under false pretences. It was no help to clear thought or any aid to debate that a profession should have attached to it so criminal a label and so vile a libel. They were told on the authority of Mr. Macquisten that a new breed of men had come into the medical profession. He would assure the House that those who were entering the medical profession proceeded to the ancient universities where they studied athletics and the humane arts, and they then entered the hospitals to be taught the same traditions of medicine as existed before the National Insurance Act was ever thought of.

He was troubled, said Dr. O'Donovan, to think that it should be thought in the House of Commons that a member of the medical profession ought to be perfectly content to maintain his family on a salary of £300 a year; that he should live until death called him in a miasma of disease and in the midst of the direst poverty on such a sum; and that, on the other hand, if he took service under the panel, and received £1500 a year, he ought to be troubled in his conscience and refuse to work. It had been a blessing to the profession that thanks to the National Health Insurance Act doctors could now bring up their sons to that profession which they loved, and hand on from father to son the great tradition of service. He submitted that the Insurance Act had brought into the profession a wider selection of keen minds anxious to maintain the public health. The Act had worked well because it had received the coöperation of an intelligent and learned profession. Acting through the British Medical Association the medical profession had worked cordially with Governments of all colours for the people's health, and because of that coöperation the points of this Act had been good. The British Medical Association would celebrate the centenary of its foundation this year in London under the presidency of Lord Dawson, and hours would be devoted by the keenest minds to the discussion of public health problems.

Members of the medical profession, Dr. O'Donovan continued, had been drawn into public life because through the Insurance Act they had been interested in public health administration. They had not segregated themselves entirely in the atmosphere of the sick-room. Owing to this Act, which had been so much derided, our medical research through the medium of the Medical Research Council had been placed on a footing which was the admiration of Europe. Through that they had been able, with the coöperation of the large voluntary hospitals, to bring every modern device of science and the help of specialists to the home of every one of His Majesty's subjects. He apologised for delaying the House, but a corrosive acid should have some antidote. (Cheers.)

MOTION FOR REJECTION LOST.

The motion for the rejection of the Bill was rejected by 245 votes to 43, and the measure was then read a second time.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 7TH, 1932.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 68 (last week 62); scarlet fever, 1494; diphtheria, 708; enteric fever, 35; acute pneumonia (primary or influenzal), 1033; puerperal fever, 58; cerebro-spinal fever, 63; acute poliomyelitis, 5; acute polio-encephalitis, 3; encephalitis lethargica, 11; dysentery, 24; ophthalmia neonatorum, 108. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 10th–11th was as follows: Small-pox, 109 under treatment, 6 under observation (last week 106 and 2 respectively); scarlet fever, 1508; diphtheria, 1334; enteric fever, 8; measles, 2615; whooping-cough, 428; puerperal fever, 15 (plus 3 babies); encephalitis lethargica, 226; poliomyelitis, 4; "other diseases," 90. At St. Margaret's Hospital there were 14 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was no death from small-pox or enteric fever, 87 (41) from measles, 5 (3) from scarlet fever, 49 (11) from whooping-cough, 26 (7) from diphtheria, 48 (17) from diarrhœa and enteritis under two years, and 36 (5) from influenza. The figures in parentheses are those for London itself.

Liverpool reported 10 deaths from measles, Derby 5, Walthamstow and Manchester each 3. Birmingham reported 5 deaths from whooping-cough, Manchester 4, and Liverpool 3. Three fatal cases of diphtheria were reported at Tottenham and at Hull.

The number of stillbirths notified during the week was 316 (corresponding to a rate of 45 per 1000 births), including 56 in London.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comdr. S. W. Grimwade is placed on the retd. list at his own request with rank of Surg. Capt.

Surg. Lt.-Comdr. T. C. H. Neil to *Ceres*.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. G. B. F. Churchill, having attained the age for compulsory retirement, is placed on retd. pay.

J. W. A. MacIver to be Lt. (on prob.).

ARMY DENTAL CORPS.

Lt. W. G. Martin to be Capt.

TERRITORIAL ARMY.

Capt. G. Bailey resigns his commn. and retains his rank with permission to wear the prescribed uniform.

Capts. P. Mumford and K. V. Bailey resign their commns.

Lt. W. A. Ball to be Capt.

Lt. R. Jackson resigns his commn.

INDIAN MEDICAL SERVICE.

The undermentioned Capts. (prov.) (on prob.) are confirmed in their rank: Capts. (on prob.) R. R. Bakhshi, D. C. Chopra, and M. Jafar.

CORRESPONDENCE

APPENDICITIS.

To the Editor of THE LANCET.

SIR,—I have read with great appreciation the lecture of my old friend. Sir James Berry, on "Fallen dols." Making all allowance for inaccuracy of old mpressions and for defaults of memory there can, think. be little doubt that appendicitis is far more requently seen in hospital wards than "perityphlitis" ever was. I can recall a few cases. seen in student days. of abscess in the right iliac fossa which pointed, or of abscess in the pelvis which emptied through the rectum. I clearly remember cases of general peritonitis which on the post-mortem table showed phacelation and rupture of the appendix; and I recall that "Wilks and Moxon" described similar conditions. I hold firmly to the opinion. which I have endeavoured to express to generations of medical students, that "no one should ever die of appendicitis," and I have also affirmed with equal truth and emphasis that deaths in this disease are too often "therapeutic"—caused, that is, by active measures designed for relief.

In olden days all cases which would now be classed as "appendicitis" were treated. in medical wards of course. by starvation and by administration of calomel and opium, one-quarter grain of each every four hours. When abdominal surgery first entered upon its startling career, that great pioneer. Lawson Tait, advocated with characteristic vigour the aperient treatment of the peritonitis that not seldom followed operation. Surgeons everywhere were encouraged to give, and often to repeat. large doses of purgatives of the most active and turbulent character. When, therefore, abdominal distension and intestinal paresis were observed in cases of "perityphlitis." which Reginald Fitz was teaching us to call "appendicitis." surgeons turned with enthusiasm, and with disastrous consequences, to purgatives to bring relief. From that custom, almost alone, the whole prospect *before* patients has undergone a bitter change. Harvey Cushing showed long ago that the cæcum, terminal ileum, and lowest part of ascending colon. have the highest bacterial content; and that micro-organisms therein are possessed of greatest virulence. One effect of aperients is to increase secretion; another, to arouse greatly strengthened muscular contraction. If the lumen of the appendix is blocked, and if the obstructive agent cannot be expelled by the agitation caused by purgatives, perforation will occur and the material extravasated into the peritoneum will then be of most infective power. I can hardly expect it to be credited, but it is nevertheless true, that for over twenty years I have not operated upon one single case of perforation (I exclude gangrene without perforation) in which an aperient had not been given. The philocathartic propensities of mothers and grandmothers (especially grandmothers!) lead them to administer castor oil or some equally active purgative to children who complain of "stomach ache." The most precious rule of all is, however, *avoid aperients*. Were this rule observed we should rarely see "therapeutic peritonitis" in children.

My view of treatment in cases of appendicitis may therefore be briefly and categorically stated :—

(1) Early operation in all cases is the best; by "early" is meant within four or six hours of the onset of the invariable inaugural symptom pain.

(2) If an aperient has been given operation at the earliest possible moment is imperative. Whatever risks are then taken will almost certainly be less than the risks of delay. The patient's condition may dictate a simple swift procedure, and a local anæsthetic. "Get in quick, get out quicker," as J. B. Murphy taught.

(3) If no aperient has been given. starvation, opium, absolute rest may enable a deliberate leisurely choice to be taken, in favour either of operation or of delay until resolution or suppuration occur. Such suppuration will always be local. and vent may be given by abdominal incision over the centre of the abscess, or by incision made in a few seconds into an abscess presenting in the vagina or protruding into the rectum. Such low openings lead to quicker healing than any others; and when. two weeks later, the appendix is removed, the surgeon will be surprised to find how little evidence remains of suppuration.

Ruthless operation with large incisions and a mind set upon removal of the appendix when an abscess is opened are, I cordially agree with Sir James Berry, entirely out of place. May I thank him for a most timely and sagacious contribution to a subject in regard to which wisdom has not yet descended upon us all? I am, Sir, yours faithfully,

Leeds, May 14th, 1932. MOYNIHAN.

To the Editor of THE LANCET.

SIR,—I have examined the statistics of the cases of appendicitis which have been under the care of the staff in St. Thomas's Hospital since the year 1869. The result is very striking, more especially when we consider that in many instances several of those who came for hospital treatment had been under care by general practitioners for one or perhaps five previous attacks. As the numbers of this disease treated at St. Thomas's are equalled or possibly surpassed by those admitted to other London hospitals, whilst private nursing homes are seldom without cases of operation for this disease, it has been considered advisable to approach THE LANCET to suggest an inquiry into the causation of appendicitis and its spread in recent years.

It is an investigation which cannot be carried out by private individuals, and we have thought that THE LANCET, with its record of help to the profession (during past years), would most efficiently carry out such investigation to a successful result. I am permitted to add the names of Sir Percy Sargent, senior surgeon to St. Thomas's, and Dr. A. E. Russell, consulting physician. St. Thomas's, in this suggestion.

I am, Sir, yours faithfully,

W. H. BATTLE,
Consulting Surgeon, St. Thomas's.
Harley-street, W., May 11th, 1932.

To the Editor of THE LANCET.

SIR,—In his address to the Medical Society of London Sir James Berry has revived an old controversy which most surgeons had considered settled. During the period that Sir James was surgical registrar at St. Bartholomew's I was house surgeon to Mr. Howard Marsh and his junior. Mr. Bowlby (as he then was). and can claim to have been brought up in the conservative school, better styled perhaps. the school of "delayed action." In those days it frequently happened that appendix cases were not admitted until a swelling had called attention to the necessity for surgical treatment. The acute fulminating cases were too often labelled as peritonitis, and failed to reach hospital in the operable stage, or if they did, often failed to survive. The statistics *which Sir James gives of a series of cases admitted* to the medical wards give no true picture of the mortality of appendicitis at that time.

The expectant policy which Sir James advocates in cases which have become localised and are developing an abscess is a policy of safety which was very commonly adopted in those days, and is perhaps not followed as often as it should be at the present time. I am in agreement with him with regard to the dangers of feeding, purgatives, &c., when an expectant policy is being adopted, and also as to the risks of approaching an inflammatory mass via the peritoneal cavity. I cannot, however, help feeling that Sir James in his address has lost sight of the very important fact that there are two distinct types of the acute appendix.

(1) There is the acute inflammatory (non-obstructive) type which is ushered in with malaise, rise of temperature, tenderness, and pain which is ultimately localised to the appendix region. Many of these cases subside under appropriate expectant treatment although, if diagnosed and operated on early, they run on the whole less risk than by expectant treatment. The best policy to adopt in this type of case is a matter of opinion, and each case must be judged on its merits.

(2) The other type is the acute obstructive (or mechanical) appendix, which has an entirely different onset, with sudden severe pain and vomiting which continues unless spontaneous relief occurs. In these cases there is seldom any warning, and no initial malaise or inflammatory signs. It is these cases, where a stercolith occludes the lumen, which fulminate rapidly, unless spontaneous relief occurs, and end *in gangrene and perforation. When perforation* occurs there is often sudden relief of both pain and distress and a short quiescent period results which may be most misleading, until the signs of peritonitis develop. The absence of inflammatory signs and the sudden cessation of acute symptoms sometimes give rise to a faulty diagnosis of intestinal colic. To delay operation in this type an hour longer than is absolutely necessary is to run a very grave risk. To deliberately adopt a waiting policy when an obstruction has been diagnosed is to invite perforation and disaster, and a policy such as this must be responsible for many deaths.

Prof. D. P. D. Wilkie, not long since, called attention in the medical press to the importance of recognising these two types, and for many years I have taught students the importance of distinguishing between these two classes and the urgent necessity for prompt treatment in the obstructive cases. It is true that after the first 24 hours or so the two types often cannot be distinguished, because inflammatory signs are added to the obstructive, but it is in the first 24 hours that the great risk of perforation and general peritonitis occurs, which can and should be avoided if diagnosis is sound and the urgency realised.

I venture to think that Sir James Berry, by omitting to refer to this type of case, may mislead many, and in so doing be responsible for more lives being lost than might be saved by following his precepts in other types of appendix inflammation.

I am, Sir, yours faithfully,

London, W., May 16th, 1932. C. GORDON-WATSON.

QUININE IN THE MÉNIÈRE SYNDROME.

To the Editor of THE LANCET.

SIR,—In a paper on the treatment of the Ménière syndrome (THE LANCET, Feb. 6th, p. 285) Mr. Keen *makes the statement that* "quinine should be avoided." I am convinced that if this advice is strictly followed out a great deal of relief will be withheld from many sufferers. The administration of such small doses as gr. ½–1, two or three times a day, has often produced the most gratifying effect. At the West End Hospital for Nervous Diseases my colleagues referred to me cases presenting the Ménière symptoms, and in a consecutive series of 48, the effect of small doses of quinine was tested. In 12 no report was obtainable, and of the remaining 36, there was in 28 well-marked and in 2 doubtful, improvement, while in 6 there was none. In these 6, the diagnoses were climacteric congestion of the labyrinth, hysteria, labyrinthine congestion, doubtful labyrinthine effusion, intense neurasthenia, indefinable vertigo. They were, therefore, not clear-cut *cases.*

The other cases presented the ordinary features of a damaging lesion of the labyrinth of one side, and the vertigo depended mainly on the asymmetrical action of the two labyrinths. The beneficial effect was probably due to the sedative action of the quinine on the sound one. In such cases the administration of quinine in small doses sufficient to quiet the equilibrial labyrinth without materially affecting the hearing is very efficacious, even if it only breaks the vicious circle and removes the apprehension of further attacks until "compensatory" equilibrium is restored. That the beneficial result was really due to the quinine was proved by the fact that the substitution of quassia for quinine in a number of cases was followed by recurrence of the vertigo which subsided when quinine was again administered.

My favourable opinion of the value of this treatment is endorsed by Prof. Albert Ramsbottom (THE LANCET, 1924, ii., 1191), who writes as follows: "On the whole, however, I believe that quinine in small doses with or without bromide will be found to be the most valuable drug in warding off attacks of vertigo of this class," viz., a non-suppurative lesion in the labyrinth. He prescribed it as follows: Quin. sulph. gr. ½, acid. hydrobrom. dil., ♏ xv., tinct. aurantii, ♏ xx., aq. ad ½ oz. I am sure it will be found useful in genuine cases.

I am, Sir, yours faithfully,

London, May 10th, 1932. JAMES DUNDAS-GRANT.

"EXCESSIVE SURGERY."

To the Editor of THE LANCET.

SIR,—In your issue of May 14th (p. 1047) Mr. F. M. Loughnane is reported *to have said in a* discussion on excessive surgery that "Hurst admitted that 20 per cent. of chronic gastric ulcer cases died of carcinoma." I have never made any such gross travesty of the truth. I have no figures of my own but I have often quoted Prof. M. J. Stewart's very accurate investigations which showed that among 180 chronic gastric ulcers removed at operation and specially studied from this point of view 11, or 6·1 per cent., showed evidence of becoming malignant. As only the more severe cases of ulcer, in which medical treatment has failed, are likely to come to operation, the percentage undergoing malignant degeneration is probably much less than this.

Mr. Loughnane added that "laparotomy did no larm and made it possible to prevent the onset of arcinoma.” The second statement is no doubt rue if partial gastrectomy is performed, but with in *average* mortality of at least 10 per cent. and with the definite (though now preventable) risk of severe achlorhydric anæmia developing as a sequel to the operation the first statement cannot be accepted. My own experience is that with very few exceptions gastric ulcers heal completely with adequate medical treatment, and Stewart has shown that the risk of carcinoma developing in the cicatrix is negligible.

In the rare cases of failure with medical treatment I have no hesitation in advising a gastrectomy sufficiently extensive to produce complete achlorhydria, but all palliative operations such as gastro-jejunostomy and jejunostomy have no advantage whatever over medical treatment and do not remove the small risk of malignant degeneration in the future.

I am, Sir, yours faithfully,

May 16th, 1932. ARTHUR F. HURST.

TRAINING IN TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—I notice that so far there has been no reply to the chief points of Dr. Davidson's admirable letter in your issue of April 30th (p. 954). I am writing because my work for the last 12 years as physician in charge of the tuberculosis department at St. Thomas's Hospital, which includes the teaching of students, has led me to form very decided views on the problems of how students should be taught and what they should know.

1. How should students be taught? Dr. Davidson favours a compulsory course, just as specialists in the numerous special departments ask for a compulsory course in their particular subject. The department at St. Thomas's is self-contained. It includes an out-patient department, a borough dispensary, a tuberculosis ward, and a lady almoner's and after-care section; and in addition there are facilities for all the special investigations afforded by a general hospital. In my opinion, a student can obtain at least a satisfactory knowledge of the subject if he spends one morning a week in the out-patient room and one in the ward, over a period of three months. I regard it as essential that the numbers of students should be limited to four in the out-patient room and to 16 at the visit to the ward. The limitation in the out-patient room is important, not only from the point of view of the patients, but especially from that of the students. Each student needs individual attention, and the teaching on any particular case must be adapted to the capacity of the student concerned. What may be a useful and illuminating suggestion to a clever student often produces a dangerous perversion of the truth in the mind of one less gifted. So I try to keep the out-patient classes small, and as far as possible I grade them according to capacity. It follows that I cannot teach more than 64 students a year as I think they should be taught, yet the department is not a small one, for the new cases average 2000 a year and there is work for two whole-time medical officers. If the course were made compulsory the scope of the department would have to be increased, and I might not get the interest and attention which are usually shown by the volunteer.

2. What should students know? In the ward they should learn the general clinical aspect and the modern methods of diagnosis and treatment, from a systematic course of clinical lectures. But they need something more practical as well. The majority of students become general practitioners, and they will then require to know: (1) what cases to suspect; (2) how to make use of the local tuberculosis scheme; (3) how to treat complications; (4) how to recognise recrudescence of activity; (5) how the limitations imposed by treatment and by the disease itself will affect the patient in his work and environment; (6) what can be done to prevent spread of the disease. I maintain that subjects such as these should be taught in a dispensary.

At St. Thomas's eight whole-time clinical assistants each year receive special training, but organised post-graduate teaching is not undertaken, and therefore I am not qualified to discuss it. It is, however, a question which must be taken into account when training in tuberculosis is under review.

In conclusion, I would plead that for adequate instruction in tuberculosis a carefully organised department, including a tuberculosis dispensary, and a systematic and practical course of teaching are both essential elements, especially if that instruction is compulsory.—I am, Sir, yours faithfully,

G. T. HEBERT, M.D., F.R.C.P.

Harley-street, W., May 12th, 1932.

To the Editor of THE LANCET.

SIR,—I note with satisfaction the comments of the secretary of the University of Aberdeen on my letter in your issue of April 30th. My statements were based on a communication sent to me by the Joint Tuberculosis Council containing a digest of information supplied to that council by the deans or secretaries of various medical schools. From this it was by no means clear either that the training in tuberculosis at Aberdeen was compulsory for the M.B. degree, or that any definite coöperation existed between the municipal authorities and the university. In view of the admiration I have always felt for the clinical teaching at the Aberdeen School, I sincerely hope that my observations may not be misconstrued as intending any adverse criticism, and I am grateful to Mr. Butchart for pointing out this unintentional error on my part.

I am, Sir, yours faithfully,

MAURICE DAVIDSON.

Wimpole-street, W., May 13th, 1932.

CŒLIAC DISEASE AND DWARFISM.

To the Editor of THE LANCET.

SIR,—Dr. Vaughan and Dr. Hunter in their reply to my letter again ignore the carefully worded statement of our original article to the effect that the case had been considered to be renal only before our examination. I can only emphasise for the third time that we never at any time considered the cause to be renal.

This, however, is beside the point.

I may perhaps mention that at the time this investigation was carried out Dr. Hampson and myself were specially interested in sprue and cœliac disease, and were on the lookout for the evidence of either in all the cases of megalocytosis investigated by us. We were equally alive to the fact that the symptoms of cœliac disease might not be a prominent feature of the case. I can only repeat that the finding mentioned in our article of a “slight excess of soap crystals” in one single specimen of a series examined especially for their presence cannot be accepted as a finding in any way suggestive of cœliac admitted until a swelling had called attention to the necessity for surgical treatment. The acute fulminating cases were too often labelled as peritonitis, and failed to reach hospital in the operable stage, or if they did, often failed to survive. The statistics which Sir James gives of a series of cases admitted to the medical wards give no true picture of the mortality of appendicitis at that time.

The expectant policy which Sir James advocates in cases which have become localised and are developing an abscess is a policy of safety which was very commonly adopted in those days, and is perhaps not followed as often as it should be at the present time. I am in agreement with him with regard to the dangers of feeding, purgatives, &c., when an expectant policy is being adopted, and also as to the risks of approaching an inflammatory mass via the peritoneal cavity. I cannot, however, help feeling that Sir James in his address has lost sight of the very important fact that there are two distinct types of the acute appendix.

(1) There is the acute inflammatory (non-obstructive) type which is ushered in with malaise, rise of temperature, tenderness, and pain which is ultimately localised to the appendix region. Many of these cases subside under appropriate expectant treatment although, if diagnosed and operated on early, they run on the whole less risk than by expectant treatment. The best policy to adopt in this type of case is a matter of opinion, and each case must be judged on its merits.

(2) The other type is the acute obstructive (or mechanical) appendix, which has an entirely different onset, with sudden severe pain and vomiting which continues unless spontaneous relief occurs. In these cases there is seldom any warning, and no initial malaise or inflammatory signs. It is these cases, where a stercolith occludes the lumen, which fulminate rapidly, unless spontaneous relief occurs, and end in gangrene and perforation. When perforation occurs there is often sudden relief of both pain and distress and a short quiescent period results which may be most misleading, until the signs of peritonitis develop. The absence of inflammatory signs and the sudden cessation of acute symptoms sometimes give rise to a faulty diagnosis of intestinal colic. To delay operation in this type an hour longer than is absolutely necessary is to run a very grave risk. To deliberately adopt a waiting policy when an obstruction has been diagnosed is to invite perforation and disaster, and a policy such as this must be responsible for many deaths.

Prof. D. P. D. Wilkie, not long since, called attention in the medical press to the importance of recognising these two types, and for many years I have taught students the importance of distinguishing between these two classes and the urgent necessity for prompt treatment in the obstructive cases. It is true that after the first 24 hours or so the two types often cannot be distinguished, because inflammatory signs are added to the obstructive, but it is in the first 24 hours that the great risk of perforation and general peritonitis occurs, which can and should be avoided if diagnosis is sound and the urgency realised.

I venture to think that Sir James Berry, by omitting to refer to this type of case, may mislead many, and in so doing be responsible for more lives being lost than might be saved by following his precepts in other types of appendix inflammation.

I am, Sir, yours faithfully,

London, W., May 16th, 1932. C. GORDON-WATSON.

QUININE IN THE MÉNIÈRE SYNDROME.

To the Editor of THE LANCET.

SIR,—In a paper on the treatment of the Ménière syndrome (THE LANCET, Feb. 6th, p. 285) Mr. Keen makes the statement that "quinine should be avoided." I am convinced that if this advice is strictly followed out a great deal of relief will be withheld from many sufferers. The administration of such small doses as gr. ½–1, two or three times a day, has often produced the most gratifying effect. At the West End Hospital for Nervous Diseases my colleagues referred to me cases presenting the Ménière symptoms, and in a consecutive series of 48, the effect of small doses of quinine was tested. In 12 no report was obtainable, and of the remaining 36, there was in 28 well-marked and in 2 doubtful, improvement, while in 6 there was none. In these 6, the diagnoses were climacteric congestion of the labyrinth, hysteria, labyrinthine congestion, doubtful labyrinthine effusion, intense neurasthenia, indefinable vertigo. They were, therefore, not clear-cut cases.

The other cases presented the ordinary features of a damaging lesion of the labyrinth of one side, and the vertigo depended mainly on the asymmetrical action of the two labyrinths. The beneficial effect was probably due to the sedative action of the quinine on the sound one. In such cases the administration of quinine in small doses sufficient to quiet the equilibrial labyrinth without materially affecting the hearing is very efficacious, even if it only breaks the vicious circle and removes the apprehension of further attacks until "compensatory" equilibrium is restored. That the beneficial result was really due to the quinine was proved by the fact that the substitution of quassia for quinine in a number of cases was followed by recurrence of the vertigo which subsided when quinine was again administered.

My favourable opinion of the value of this treatment is endorsed by Prof. Albert Ramsbottom (THE LANCET, 1924, ii., 1191), who writes as follows: "On the whole, however, I believe that quinine in small doses with or without bromide will be found to be the most valuable drug in warding off attacks of vertigo of this class," viz., a non-suppurative lesion in the labyrinth. He prescribed it as follows: Quin. sulph. gr. ½, acid. hydrobrom. dil., ♏ xv., tinct. aurantii, ♏ xx., aq. ad ½ oz. I am sure it will be found useful in genuine cases.

I am, Sir, yours faithfully,

London, May 10th, 1932. JAMES DUNDAS-GRANT.

"EXCESSIVE SURGERY."

To the Editor of THE LANCET.

SIR,—In your issue of May 14th (p. 1047) Mr. F. M. Loughnane is reported to have said in a discussion on excessive surgery that "Hurst admitted that 20 per cent. of chronic gastric ulcer cases died of carcinoma." I have never made any such gross travesty of the truth. I have no figures of my own but I have often quoted Prof. M. J. Stewart's very accurate investigations which showed that among 180 chronic gastric ulcers removed at operation and specially studied from this point of view 11, or 6·1 per cent., showed evidence of becoming malignant. As only the more severe cases of ulcer, in which medical treatment has failed, are likely to come to operation, the percentage undergoing malignant degeneration is probably much less than this.

Mr. Loughnane added that "laparotomy did no arm and made it possible to prevent the onset of carcinoma." The second statement is no doubt true if partial gastrectomy is performed, but with an *average* mortality of at least 10 per cent. and with the definite (though now preventable) risk of severe achlorhydric anæmia developing as a sequel to the operation the first statement cannot be accepted. My own experience is that with very few exceptions gastric ulcers heal completely with adequate medical treatment, and Stewart has shown that the risk of carcinoma developing in the cicatrix is negligible.

In the rare cases of failure with medical treatment I have no hesitation in advising a gastrectomy sufficiently extensive to produce complete achlorhydria, but all palliative operations such as gastro-jejunostomy and jejunostomy have no advantage whatever over medical treatment and do not remove the small risk of malignant degeneration in the future.

I am, Sir, yours faithfully,
ARTHUR F. HURST.
May 16th, 1932.

TRAINING IN TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—I notice that so far there has been no reply to the chief points of Dr. Davidson's admirable letter in your issue of April 30th (p. 954). I am writing because my work for the last 12 years as physician in charge of the tuberculosis department at St. Thomas's Hospital, which includes the teaching of students, has led me to form very decided views on the problems of how students should be taught and what they should know.

1. How should students be taught? Dr. Davidson favours a compulsory course, just as specialists in the numerous special departments ask for a compulsory course in their particular subject. The department at St. Thomas's is self-contained. It includes an out-patient department, a borough dispensary, a tuberculosis ward, and a lady almoner's and after-care section; and in addition there are facilities for all the special investigations afforded by a general hospital. In my opinion, a student can obtain at least a satisfactory knowledge of the subject if he spends one morning a week in the out-patient room and one in the ward, over a period of three months. I regard it as essential that the numbers of students should be limited to four in the out-patient room and to 16 at the visit to the ward. The limitation in the out-patient room is important, not only from the point of view of the patients, but especially from that of the students. Each student needs individual attention, and the teaching on any particular case must be adapted to the capacity of the student concerned. What may be a useful and illuminating suggestion to a clever student often produces a dangerous perversion of the truth in the mind of one less gifted. So I try to keep the out-patient classes small, and as far as possible I grade them according to capacity. It follows that I cannot teach more than 64 students a year as I think they should be taught, yet the department is not a small one, for the new cases average 2000 a year and there is work for two whole-time medical officers. If the course were made compulsory the scope of the department would have to be increased, and I might not get the interest and attention which are usually shown by the volunteer.

2. What should students know? In the ward they should learn the general clinical aspect and the modern methods of diagnosis and treatment, from a systematic course of clinical lectures. But they need something more practical as well. The majority of students become general practitioners, and they will then require to know: (1) what cases to suspect; (2) how to make use of the local tuberculosis scheme; (3) how to treat complications; (4) how to recognise recrudescence of activity; (5) how the limitations imposed by treatment and by the disease itself will affect the patient in his work and environment; (6) what can be done to prevent spread of the disease. I maintain that subjects such as these should be taught in a dispensary.

At St. Thomas's eight whole-time clinical assistants each year receive special training, but organised post-graduate teaching is not undertaken, and therefore I am not qualified to discuss it. It is, however, a question which must be taken into account when training in tuberculosis is under review.

In conclusion, I would plead that for adequate instruction in tuberculosis a carefully organised department, including a tuberculosis dispensary, and a systematic and practical course of teaching are both essential elements, especially if that instruction is compulsory.—I am, Sir, yours faithfully,

G. T. HEBERT, M.D., F.R.C.P.
Harley-street, W., May 12th, 1932.

To the Editor of THE LANCET.

SIR,—I note with satisfaction the comments of the secretary of the University of Aberdeen on my letter in your issue of April 30th. My statements were based on a communication sent to me by the Joint Tuberculosis Council containing a digest of information supplied to that council by the deans or secretaries of various medical schools. From this it was by no means clear either that the training in tuberculosis at Aberdeen was compulsory for the M.B. degree, or that any definite coöperation existed between the municipal authorities and the university. In view of the admiration I have always felt for the clinical teaching at the Aberdeen School, I sincerely hope that my observations may not be misconstrued as intending any adverse criticism, and I am grateful to Mr. Butchart for pointing out this unintentional error on my part.

CŒLIAC DISEASE AND DWARFISM.

To the Editor of THE LANCET.

SIR.—Dr. Vaughan and Dr. Hunter in their reply to my letter again ignore the carefully worded statement of our original article to the effect that the case had been considered to be renal only before our examination. I can only emphasise for the third time that we never at any time considered the cause to be renal.

This, however, is beside the point.

I may perhaps mention that at the time this investigation was carried out Dr. Hampson and myself were specially interested in sprue and cœliac disease, and were on the lookout for the evidence of either in all the cases of megalocytosis investigated by us. We were equally alive to the fact that the symptoms of cœliac disease might not be a prominent feature of the case. I can only repeat that the finding mentioned in our article of a "slight excess of soap crystals" in one single specimen of a series examined especially for their presence cannot be accepted as a finding in any way suggestive of cœliac disease—the more so as neither at that time nor at any previous time were the stools "pale and porridgy," as Drs. Vaughan and Hunter agree that they should have been. The patient and her parents were closely questioned on this point.

The reference to erythroblastic anæmia tends further to confuse the issue; the white cell count in the patient under discussion was *not* high, the total white count being 4800 per c.mm., with a differential count as follows: polymorphs, 50 per cent.; lymphocytes, 42 per cent.; hyaline cells, 6 per cent.; eosinophils, 2 per cent.; there were no abnormal white cells present.

Drs. Vaughan and Hunter must have notes on cases, as we have, in which megalocytosis has occurred in young children both with and without an increase in the white count, and in which repeated examinations of the stools have revealed no abnormalities; such cases occurring since the introduction of liver therapy have been cured by that treatment. Whether the white cells of young children respond in a similar manner to those of adults may be open to debate, but there is considerable evidence to the contrary—e.g., acholuric jaundice when it occurs in infancy and childhood may be associated with a white count which shows a large number of myelocytes with occasional myeloblasts, though this is not the case in adults.

Whether dwarfism can be due to the blood condition, or whether, as appears more probable in the light of more recent knowledge, both are related to a common cause must remain open to doubt, as practically all the recorded cases of Addisonian pernicious anæmia occurring in children to which Drs. Vaughan and Hunter have referred have died of the disease before obvious changes in growth could have occurred.

Considerations such as those raised by Drs. Vaughan and Hunter in their letter tend to obscure the point that the facts of the case offer no justification for its inclusion as a case of cœliac disease.

I am, Sir, yours faithfully,

Grosvenor-street, W., May 15th, 1932. J. W. SHACKLE.

UNDULANT FEVER.

To the Editor of THE LANCET.

SIR,—You may consider it profitable to add to reports of *abortus* fever in this country by publishing a record of four cases detected in this area of Lancashire between September, 1930, and April, 1932. In this laboratory, during that period, 60 sera have been searched for agglutinins against the enteric group. Six significant results have been obtained and confirmed clinically or by culture as typhoid or paratyphoid B fever. Forty-five of the above sera were searched for agglutinins against *Brucella abortus* and *melitensis*, using Oxford standard suspensions. Five positive results have been obtained, four significant, one insignificant. The average "reduced" titre of the significant results is 500, the insignificant figure being 12. The corresponding figures for the full titres are 1060 and 25. Of the significant results, two were suspected before the sera were obtained, two were unexpected in cases of unexplained fever. All four cases, when reviewed, conformed with *abortus* fever. One case was the child of a farmer, in whose herd of cows was infectious abortion. In no other case was there indication of the source of infection. In no case was obtained a positive culture.

I am, Sir, yours faithfully,

F. B. SMITH.

Pathological Laboratory, Royal Infirmary, Preston,
May 13th, 1932.

THE HEALTH OF HENRY VIII.

To the Editor of THE LANCET.

SIR,—In his interesting work upon Henry VIII., reviewed in your issue of May 14th (p. 1077), Mr. Chamberlin denies that the bluff king suffered from syphilis, thereby giving the lie direct to the late Dr. Maclaurin's conclusions set forth in his two books, "Post Mortem" and "Mere Mortals." Since Prof. Chamberlin is not himself a medical man, it may interest those of your readers who may be unacquainted with Dr. Maclaurin's books to learn the main points of the latter's arguments.

Dr. Maclaurin ("Post Mortem," p. 14), after pointing out that, following the return of Columbus's men, syphilis "ran like a whirlwind through Europe," sums up his evidence beforehand with the words: "It is impossible to doubt that Henry contracted it in his youth; the evidence will become clear to any doctor as we proceed." He mentions, en passant, the absurd charge made against Wolsey of giving the King syphilis by whispering in his ear and points out that the Cardinal had several healthy illegitimate children, adding, "On the whole it is possible that Henry caught the disease in the usual way."

In "Mere Mortals" (pp. 49–50), Dr. Maclaurin formulates his diagnostic reasons under six heads, which may be briefly summarised as follows: (1) The extraordinary number of premature births and dead children from two of his wives, one of whom was young and healthy. The issue by Katherine of Aragon was as follows: A stillbirth in 1510, Henry 1511 (lived six weeks), miscarriage 1513, premature male 1514, Mary 1516, two miscarriages 1517, and a stillborn son 1518. Anne Boleyn bore Elizabeth 1533 and a stillborn son 1536. (2) The poor health of at least three of his children, Mary, Edward VI., and the Duke of Richmond. To these I shall return later. (3) The terrible mental, moral, and physical degeneration which set in in Henry's early middle age. (4) The facts given in the *British Medical Journal* in 1910:—"From being an able and athletic man he had become a mass of loathsome infirmities. . . . His legs were swollen and covered with festering sores, causing an unbearable stench." (5) The sinus in his leg, which "seems to have been syphilitic periostitis occurring in an essentially neurotic man." (6) Death in stupor at the comparatively early age of 55. In detailing these points, Dr. Maclaurin wisely remarks, "Not any single one of these is indubitable evidence of syphilis, but taken altogether there is no other reasonable explanation," and he suggests that Henry's case may be one of those in *which lack of early treatment, combined with worry and overstrain, may* "go tragically wrong in the end."

Henry's unhealthy children present, perhaps, the most difficult problem. On the one hand we have Edward VI. who is stated to have died of consumption. It was, however, a consumption in which the boy's legs swelled, his complexion grew sallow, his hair fell out, and the terminal joints of his fingers fell off (suggestive of syphilitic dactylitis). Dr. Maclaurin, while hazarding a guess "that it was syphilis of the lung that killed him," plausibly suggests that, as in many other examples, it was a case in which the tuberculosis was complicated with congenital syphilis.

With regard to Mary, I remember how, when first I saw the portrait preserved in Winchester Cathedral, I was struck by its obvious resemblance to a case of congenital syphilis. Later I read somewhere, but cannot recall the source, that Philip of Spain complained of the disgusting odour from her nose. Naturally I was interested to find Dr. Maclaurin ("Mere Mortals," p. 81 ff.) drawing attention to the facts that she was a sickly child, suffered from severe headaches and defective vision (which Sir Clifford Allbutt suggested as possible interstitial keratitis). Mary died suddenly at 42, supposedly of ovarian tumour. Dr. Maclaurin remarks that "Any doctor looking at the portrait of her wizened, lined, and prematurely aged face would probably say 'That woman must have been a hereditary syphilitic,' especially if he knew the history of Henry VIII."

On the other hand, there are Elizabeth and the Duke of Richmond, in whom there certainly appears no evidence of syphilis. The latter, "Henry Fitzroy," was born in 1519, at the period in which Katherine of Aragon was having miscarriages and stillbirths, and when Henry was 18. Richmond was physically weak after the spring of 1536 and died of consumption July 23rd of that year, having suffered from hæmoptysis since Anne Boleyn's execution in May, the last occasion that he appeared in public. Both Henry Fitzroy and Elizabeth, born 1553, when Henry was 42, make the question of syphilis doubtful, but it is just possible that neither of them were the King's children. Into this it is, perhaps, best not to enter.

It may certainly be said, from the standpoint of the legal mind, that the question of Henry's syphilis is "non-proven," but, in the face of Dr. Maclaurin's arguments, backed up by his vast clinical experience on the subject, I do not think it can be summarily dismissed by a layman without protest.

I am, Sir, yours faithfully,
MACLEOD YEARSLEY.
Harley-street, W., May 16th, 1932.

THE GALL-BLADDER AND CARDIAC PAIN.

To the Editor of THE LANCET.

SIR,—Dr. C. H. Miller's paper in your issue of April 9th (p. 767) recalls to my mind a case which suggests a peculiar relationship between gall-bladder and heart. A sturdy hard-working man of 60 was seized one afternoon in his home with the excruciating pain characteristic of biliary colic—the first and only attack. The gall-bladder point was extremely tender on palpation. Morphia and atropine gave relief. To my surprise on putting my fingers on his pulse, this was totally irregular. Auscultation confirmed a complete arrhythmia. Digitalis was given. Twenty-four hours later normal rhythm had returned and remained. There was no detectable cardiac disease; vessel walls were somewhat thickened; blood pressure not elevated. The patient insisted on resuming his work a few days later, and during a period of three years following had no further trouble. I lost touch with him after that, but I believe he continues to enjoy robust health, four and a half years after this occurrence. In this case the biliary colic appears to have been directly responsible for the alarming disturbance of the heart's rhythm, but there was no cardiac pain.

I am, Sir, yours faithfully,
MALCOLM E. J. STALKER
Roquebrune, Cap Martin, France, May 3rd, 1932.

PUBLIC HEALTH INTELLIGENCE.

To the Editor of THE LANCET.

SIR,—May I through the courtesy of your columns bring to the notice of public health administrators the facilities that exist in the Health Organisation of the League of Nations for the supply of information relating to the detailed application of different public health methods in various countries. In addition, comparative information is available with regard to epidemiological statistics and public health legislation. The Health Organisation is willing to supply, as far as possible, data on the above branches of preventive medicine.

Inquiries are however limited to those from the heads of large administrations or the heads of scientific institutions, who should indicate the purpose for which the information is required, in view of the amount of work that unconsidered requests necessarily involve. Furthermore, inquiries should be limited to information that is not already in the medical press. All inquiries should be addressed to the Medical Director, Health Section, marked "Public Health Intelligence," League of Nations, Geneva, Switzerland.

I am, Sir, yours faithfully,
LUDWIK RAJCHMAN,
Medical Director, Health Section,
League of Nations.
Geneva, May 2nd, 1932.

CORRIGENDUM.—In Dr. Hernaman-Johnson's letter last week on the Treatment of Osteo-arthritis the word hyperthymic in line 8 should read *hypertrophic.*

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

Children and Young Persons Bill.

ON Thursday, May 12th, in the House of Commons the Children and Young Persons Bill was considered on Report and read the third time.

Whitsuntide Adjournment.

On Friday, May 13th, both Houses of Parliament adjourned for the Whitsuntide recess. The House of Commons will reassemble on Monday, May 23rd, and the House of Lords on Wednesday, May 25th.

HOUSE OF COMMONS.

WEDNESDAY, MAY 11TH.

Workmen's Compensation in the Colonies.

Mr. HICKS asked the Secretary for the Colonies what steps had been taken in British Colonies and Protectorates to give effect to the provisions of the conventions on workmen's compensation (accidents and diseases) and on sickness insurance, adopted at the seventh and tenth conferences of the International Labour Organisation.—Sir P. CUNLIFFE-LISTER replied: Three conventions relating to workmen's compensation were adopted at the seventh session of the International Labour Conference. Of these, the convention relating to workmen's compensation for accidents has not been ratified in respect of the United Kingdom. The question of applying this convention to the British Colonies and Protectorates, in accordance with the provisions of Article 421 of the Treaty of Versailles, does not therefore arise. The convention relating to equality of treatment for national and foreign workers in the matter of workmen's compensation has been substantially applied in the dependencies in which workmen's compensation legislation already exists, of which particulars were given in my reply to a question on March 9th. The convention relating to workmen's compensation for occupational diseases has been applied (with suitable local variations in the diseases covered) in Malta and (so far as non-native workmen are concerned) in Northern Rhodesia. The administration of compulsory sickness insurance schemes, as contemplated in the two conventions which were adopted at the tenth session of the International Labour Conference, is not at present practicable in the Colonies and Protectorates. In the majority of the dependencies, however, free medical and hospital treatment is provided either by the Government, or (in some dependencies under statute) by large employers of organised labour. In other words, certain of the objects of these conventions are to a great extent attained without any specific contributions from the persons who derive benefit from the facilities provided.

Prison Dietary.

Mr. RHYS DAVIES asked the Home Secretary in what prisons there had been complaints and disturbances about the quality of the food supplied to prisoners; and if he would send an officer of his department to inspect the food in all prisons under his control at intervals during the year.—Sir HERBERT SAMUEL replied: Special attention has of recent years been devoted to the improvement of prison dietaries, and to securing a proper standard of skill and care in their preparation. Officers of my department regularly inspect the food and the kitchens, which are also seen by the visiting justices on their visits. It would be impracticable to collect particulars of complaints made by individual prisoners about their food, but I am satisfied that there is no general cause for complaint as regards either the quality or the preparation. There has, apart from the events of January last at Dartmoor, been no disturbance at any prison, nor any general complaint arising from dissatisfaction with the food.

Suspected Small-pox on the "Tuscania."

Mr. GROVES asked the Minister of Health whether he could state the date the child supposed to be suffering from small-pox was landed at Suez from the s.s. *Tuscania;* the date his department was informed of this fact; the date it was ascertained at Suez that the disease was chicken-pox; the date the department was notified of the change in diagnosis; and whether this information was sent by wireless to the captain of the s.s. *Tuscania* from Suez or from his department.—Sir E. HILTON YOUNG replied: The child was landed at Suez on April 22nd. The notification was received in my department on the 23rd. The diagnosis of chicken-pox was made by the Suez Hospital authorities on the 25th. My department was informed of this diagnosis, in reply to an inquiry by telegraph, on the 30th. The revised diagnosis was not notified by my department to the master of the *Tuscania*, and I have no information whether it was so notified from Suez.

THURSDAY, MAY 12TH.

The Medical Stamp Duty.

Sir ALFRED BEIT asked the Chancellor of the Exchequer whether, in view of the decline in the yield of the stamp duties, he would now consider amending the Medicine Stamp Acts with the object of rendering all medicines protected by registered names or trade marks liable to duty, even if they were of a known, admitted, or proved nature.—Mr. CHAMBERLAIN (Chancellor of the Exchequer) replied: I do not think that my hon. friend's suggestion can be accepted, but I am having the present position under the Medicine Stamp Acts examined in order to see whether some amendment of those Acts is desirable.

Public Health Law Consolidation.

Mr. LIDDALL asked the Minister of Health when the Committee on Local-Government and Public Health Law Consolidation, appointed Dec. 8th, 1930, would present its report.—Sir E. HILTON YOUNG replied: I understand that this committee hopes to issue an interim report covering the consolidation of the law of local government by the end of the present year. I cannot, at present, state when its final report will be presented.

FRIDAY, MAY 13TH.

Poison Gas Experiments.

Sir ROBERT GOWER asked the Financial Secretary to the War Office what was the number of horses, dogs, and other animals respectively used for poison gas experiments at Porton, Cambridge, and elsewhere in Great Britain respectively during the years 1930, 1931, and the first four months of 1932 respectively.—Mr. DUFF COOPER replied: The number of horses, dogs, and other animals used for chemical defence experiments at the Chemical Defence Research Establishment, Porton, and the Physiological Laboratory, Cambridge, during the periods referred to was as follows:—

—	Physiological Laboratory, Cambridge.			Chemical Defence Research Establishment, Porton.		
	Dogs.	Horses.	Other animals.	Dogs.	Horses.	Other animals.
1930	—	—	85	—	8	711
1931	—	—	11	—	—	679
1932 (Jan.–April)	—	—	—	—	—	127

No other laboratories are concerned.

MEDICAL NEWS

University of Cambridge.

On May 13th the following degrees were conferred:—

M.D.—R. K. Debenham.

M.B. & B.Chir.—H. B. Padwick.

English Conjoint Examining Board.

At the final examination, held from April 4th to 27th, the following candidates were approved in the under-mentioned subjects, but are not yet eligible for diplomas.

Medicine.—F. C. Angier, Liverpool; J. D. H. Bird, King's Coll.; R. W. Blakey, Leeds; Ethel D. M. Brook, Royal Free; B. Cates, St. Bart.'s; P. K. Chanmugam, Ceylon and King's Coll.; E. M. Clark, St. Bart.'s; H. Cohen, Middlesex; T. A. Connold, St. Thomas's; H. G. N. Cooper, Oxford and Guy's; P. T. Cooper, Camb. and St. George's; C. F. Cumings, King's Coll.; A. L. Davies, Middlesex; L. S. De Silva, King's Coll.; L. W. B. Dobbin, Camb. and London; Phyllis M. Dobbs, Royal Free; F. R. Edwards, Liverpool; Helen M. Evans, Royal Free; R. C. Evans, Univ. College; W. J. M. Evans, Cardiff; F. E. Fletcher, Bristol; D. H. Fulton, King's Coll.; Getel Gimpelson, King's Coll.; Phyllis N. Greene, Royal Free; J. C. Hardy, Univ. College; W. Hunt, Camb. and St. Bart.'s; J. E. Jones, Liverpool; Katherine M. Jones, Royal Free; M. Katz, St. Bart.'s; B. S. Kaushal, Punjab and Middlesex; L. O'N. Knox, Guy's; Peggy Levi, Birmingham; S. Livni, London; Barbara R. Lockwood, Royal Free; J. L. Lovibond, Camb. and Middlesex; Monica Low, Royal Free; I. R. W. Merrick, King's Coll.; G. R. Morgan, St. Bart.'s; R. B. Munro, Univ. College; Elizabeth M. Ogden, King's Coll.; N. C. R. M. Perumal, Ceylon and West London; Joyce A. Pope, Manchester; L. E. J. Poulier, Ceylon and St. George's; J. F. P. Price, King's Coll.; T. G. Richards, Liverpool; R. H. Rushton, King's Coll.; B. F. B. Russell, St. Bart.'s; H. B. C. Sandiford, St. Thomas's; R. T. Shipman, St. Thomas's; F. Summers, King's Coll.; Enid A. Taylour, Bristol; Patricia I. Unsworth, Liverpool; C. U. Wickham, Birmingham.

Surgery.—T. Abdel Rahman, Royal Free; H. Ackers, Liverpool; R. M. Alford, St. Thomas's; N. Bakhru, Bombay and London; J. B. Bamford, St. Bart.'s; V. H. Barnett, Univ. College; C. G. Batty-Smith, Camb. and St. George's; G. T. Bevir, Bristol; S. E. Birdsall, Camb. and St. Bart.'s; A. Birnbaum, London; Marjorie Bolton, Royal Free; E. Braithwaite, Oxford and London; T. Bromberg, St. Mary's; D. G. W. Brown, Liverpool; W. Bullock, Liverpool; L. I. S. Campbell, Camb. and Guy's; W. M. Capper, St. Bart.'s; A. Carling, Oxford and St. Thomas's; A. C. Cox, Oxford and Guy's; S. M. Cruz, Birmingham; F. J. Curtis, Camb. and Guy's; Phyllis E. Dain, Birmingham; D. T. Davies, Cardiff and St. Bart.'s; D. J. Dawson, St. Bart.'s; M. E. Disney, London; M. H. Evans, Oxford and Middlesex; S. T. Falla, London; T. B. Field, Univ. College; R. J. K. Fleming, London; F. E. Fletcher, Bristol; Fanny C. Fraser, Royal Free; A. H. Galley, King's Coll.; T. H. Gardener, London; A. K. Guha, Manchester; M. A. F. A. Hadi, Birmingham; M. Hafezi, St. Mary's; H. G. Hanley, Liverpool; P. L. S. Hatton, St. Bart.'s; L. P. Hodgson, Birmingham; E. K. Hole, St. Bart.'s; Phyllis L. Holliday, Camb. and Leeds; H. D. Holt, Univ. College; J. S. Horsley, London; A. W. J. Houghton, St. Bart.'s; T. G. Hovenden, Oxford an

Middlesex; G. S. N. Hughes, St.

London; J. L. S. James, Bristol;

S. O. Jones, King's Coll.; H. B. D

Bart.'s; M. Klass, St. Mary's;

Guy's; A. Kobylivker, Guy's;

S. Levontin, London; R. S. Lewis

L. H. B. Light, Camb. and St. Thomas's; J. N. McA

Univ. College; J. D. Macleod, St. Thomas's; H. A. Magnus, St. Bart.'s; R. L. Mansi, St. Bart.'s; G. A. Miller, Camb. and Guy's; C. J. Morgan, St. Bart.'s; C. C. Morgans, Camb. and St. Thomas's; H. F. Moseley, Oxford and St. Thomas's; G. H. C. Ovens, St. Mary's; J. W. M. Owen, St. Mary's; R. W. Pickering, Guy's; W. S. Pitt-Payne, Guy's; G. A. Powell-Tuck, Birmingham; H. G. Rees, Middlesex; A. E. A. Ridgway, Charing Cross; T. J. Ryan, St. Bart.'s; A. G. Salaman, Camb. and London; F. W. Shepherd, Camb. and St. Bart.'s; J. Shields, Camb. and St. Bart.'s; V. C. Snell, Camb. and St. Bart.'s; E. J. Somerset, King's Coll.; W. H. C. Spooner, St. Mary's; W. G. Stanford, Guy's; J. E. Stephens, St. Thomas's; F. R. Store, Univ. College; K. W. Stroude, Liverpool; E. J. Stubbs, Guy's; M. M. Syddiq, Punjab; N. S. Taylor, King's Coll.; H. R. Thompson, Camb. and London; R. E. S. Turner, Oxford and St. Bart.'s; E. A. Webb, Guy's; R. F. Winckworth, St. Thomas's; K. E. L. Yuill, Birmingham.

Midwifery.—F. C. Abeyesekera, King's Coll.; H. Ackers, Liverpool; C. F. S. Aiken, Oxford and Middlesex; I. G. Anderson, King's Coll.; I. B. Asafu-Adjaye, Univ. College; H. J. B. Atkins, Oxford and Guy's; Margaret M. Baddeley, Royal Free; R. H. Bailey, Camb. and King's Coll.; Helen Baker, Royal Free; W. N. W. Barns, Univ. College; S. A. Bather, Oxford and Leeds; R. Bennett, Oxford and St. Bart.'s; J. G. Bentley, St. Bart.'s; J. H. Bentley, Camb. and Middlesex;

R. N. Bhatia, Camb. and St. Bart.'s; H.

S. E. Birdsall, Camb. and St. Bart.'s; A

A. Bowen-Davies, Camb. and Guy's; C.

D. G. W. Brown, Liverpool; T. J. K.

W. Bullock, Liverpool; H. W. Burge

Buxton, Camb. and St. George's; H. F.

H. K. Childs, St. Thomas's; C. A. Clarke, Camb. and Guy's; C. C. Cobb, Oxford and St. George's; J. C. Colbeck, Guy's; Gwendolen N. Cook, Royal Free; D. M. Cooper, St. Thomas's;

nna V. K. Cyriax, Univ. College; D. J. Dawson, St. Bart.'s; Doris A. Dean, Birmingham; A. K. Deb, Calcutta; C. J. D'Monte, Middlesex; E. J. Dennison, St. Thomas's: L. W. B. Dobbin, Camb. and London; A. G. Donald, Guy's; J. F. H. Eagles, Bristol; F. R. Edwards, Liverpool; Evelyn M. Eggleton, Univ. College; H. L. Ellis, Middlesex; Helen M. Evans, Royal Free; W. J. M. Evans, Cardiff; L. H. Evelyn, Guy's; T. B. Field, Univ. College; R. J. K. Fleming, London; Fanny C. Fraser, Royal Free; L. B. Furber, St. Bart.'s; D. W. Geidt, Oxford and Guy's; S. K. Ghosh, Middlesex; W. G. Gill, Camb. and Guy's; T. D. M. Gillies, St. Thomas's; G. P. Goodwin, Camb. and St Mary's; D. R. Gray, Camb. and Charing Cross; N. C. Griffin, Leeds; A. V. Griffiths, Cardiff; A. K. Guha, Manchester; G. L. Hardman, St. George's; K. W. Hardy, London; Freda M. B. Harmer, Royal Free; E. H. C. Harper, St. Thomas's; P. G. F. Harvey, St. Bart.'s; O. S. Heyns, Univ. College; H. M. Hodgkin, Camb. and Guy's; L. P. Hodgson, Birmingham; T. R. Hornby, Manchester; T. G. Hudson, St. Thomas's; D. M. Hughes, Cardiff; M. G. H. Hughes, London; T. P. E. Hughes, Oxford and Middlesex; W. H. Hughes, St. Mary's; Elizabeth M. Hutton, Royal Free; H. V. D'A. Iles, Guy's; Ursula Y. im Thurn, Univ. College; J. R. E. James, Cardiff and London; D. K. Jardine, St. Bart.'s; Ruby D. Johnson, Oxford and Univ. College; Katherine M. Jones, Royal Free; Nellie E. Jones, Cardiff; A. H. Knowles, Camb. and St. Thomas's; Hilda I. Lanceley, King's Coll.: C. B. Lanyon, Univ. College; M. Lee, St. Thomas's; Z. Lefkovitz, Cardiff; F. X. Letellier, Univ. College; B. S. Lewis, St. Bart.'s; L. A. Lewis, Cardiff; W. Lewis, Camb. and Guy's; W. L. Lister, St. Mary's; D. B. McGavin, Camb. and St. Bart.'s; J. C. McGregor, Charing Cross; B. M. McOwan, St. Bart.'s; G. A. Mais, St. Thomas's; Gwendolen E. Matthews, Westminster; R. F. Matthews, Middlesex; J. B. Mee, Birmingham; H. N. Miles, King's Coll.; R. J. G. Morrison, St. Bart.'s; H. Mower, St. George's; J. B. C. Murdoch, Camb. and Guy's; L. R. Norsworthy, St. Bart.'s; R. M. M. C. Orpwood, St. Bart.'s; E. D. Page, St. Mary's; R. Q. Parkes, Camb. and St. Thomas's; E. B. Pawson, Camb. and St. Bart.'s; R. V. Payne, Camb. and Guy's; C. J. P. Pearson, St. Thomas's; N. C. R. M. Perumal, Ceylon and West London; G. E. Phillips, Cardiff; G. Phipps, St. Thomas's; A. G. Potts, Guy's; A. U. Prodhan, Calcutta; R. G. Pulvertaft, Camb. and St. Thomas's; G. Ransome, St. Bart.'s; T. G. Richards, Liverpool; A. E. G. Ridgway, London; A. H. W. Roffey, King's Coll.; Constance M. Rostron, Manchester; N. S. Sablin, St. Bart.'s; C. A. J. Sampson, St. Thomas's; R. D. Scriven, Westminster; A. L. Secchi, St. Thomas's; S. S. Selladurai, Ceylon and Middlesex; S. K. Sen, Camb. and St. Bart.'s; F. M. Shaw, Royal Free; G. H. Shaw, Camb. and St. Thomas's; J. W. V. Sheldon, Guy's; S. C. Shore, Guy's; J. P. Singer, Camb. and Guy's; H. G. Stanton, St. Bart.'s; K. W. Stroude, Liverpool; E. J. Stubbs, Guy's; N. S. Taylor, King's Coll.; D. M. E. Thomas, St. Bart.'s; F. W. Thomas, Cardiff; R. W. H. Thomas, St. Mary's; W. E. Thomas, Cardiff; H. R. Thompson, Camb. and London; A. S. Thorley, Univ. College; H. A. Treble, Oxford and Guy's; T. M. Tyrrell, Camb. and St. Thomas's; Annie M. B. Walker, Bristol; E. O. Walker, Camb. and Bristol; G. L. Ward, Camb. and St. George's; C. J. T. Watson, Camb. and St. George's; G. C. Welply, St. Mary's; W. H. Whiles, King's Coll.; C. U. Wickham, Birmingham; Albertine L. Winner, Univ. College; H. R. I. Wolfe, St. Thomas's; C. W. B. Woodham, St. Bart.'s; A. R. Woodforde, St. Bart.'s.

Pathology.—T. Abdel-Rahman, Royal Free; Winifred L. Acraman, Cardiff; P. H. Addison, St. Mary's; W. O. Baird, Middlesex; J. B. Bamford, St. Bart.'s; R. Bennett, St. Bart.'s; J. G. Bentley, St. Bart.'s; R. N. Bhatia, St. Bart.'s; J. R. Blackburne, St. Bart.'s; G. W. Blomfield, Leeds; H. W. Burge, King's Coll.; S. J. Chesser, Camb. and St. Thomas's; E. L. Cohen, Camb. and St. Bart.'s; H. Cohen, Middlesex; Gwendolen N. Cook, Royal Free; S. W. Cooper, St. Mary's; F. E. Corea, St. Bart.'s; H. Creditor, Univ. College; A. R. Cutlack, St. Bart.'s; A. L. Davies, Middlesex; D. T. Davies, Cardiff and St. Bart.'s; J. Davies, Cardiff and London; E. Davis, Manchester; W. Dean, Westminster; A. G. Donald, Guy's; R. M. Ebeid, Birmingham; M. H. Evans, Oxford and Middlesex; L. H. Evelyn, Guy's; E. D. Falconer, Guy's; T. Fichardt, Guy's; J. Fishman, London; R. J. K. Fleming, London; J. L. Freer, Guy's; S. K. Ghosh, Middlesex; G. P. Goodwin, Camb. and St. Mary's; J. L. Hamilton-Paterson, Univ. College; K. W. Hardy, London; B. A. E. Harley, Middlesex; B. P. Harris, Camb. and Middlesex; P. G. F. Harvey, St. Bart.'s; E. K. Hole, St. Bart.'s; J. Holme, Manchester; H. D. Holt, Univ. College; R. A. Hooper, Camb. and St. Thomas's; J. Howkins, Middlesex; M. G. H. Hughes, London; W. H. Hughes, St. Mary's; Elizabeth M. Hutton, Royal Free; J. R. E. James, London; W. L. James, Guy's; A. G. Johnson, Guy's; Grace M. Jones, Cardiff; Nellie E. Jones, Cardiff: G. E. Kerr, King's Coll.; B. H. Kirman, King's Coll.; R. G. Knight, Camb. and Guy's; A. Kobylivker, Guy's; C. B. Lanyon, Univ. College; S. B. Lavine, Middlesex; J. B. Lee, Manchester; A. R. R. Le Fleming, Camb. and St. Thomas's; C. A. Lewis, Camb. and King's Coll.; Vida L. Liddell, Leeds; M. B. Lindsay, St. Thomas's; B. McArdle, Guy's; J. J. McCann, St. Thomas's; R. G. Macfarlane, St. Bart.'s; B. M. McOwan, St. Bart.'s; J. I. Maran, Univ. College; J. B. Maurice, Oxford and St. Mary's; F. S. A. Maw, Camb. and King's Coll.; C. R. Mayou, Birmingham; R. V. F. Mercer, Camb. and St. Bart.'s; H. N. Miles, King's Coll.; K. O. Milner, Leeds; F. C. Moll, Westminster; R. J. G. Morrison, St. Bart.'s; J. A. Nunn, Oxford and St. Bart.'s; Elizabeth M. Ogden, King's Coll.; T. G. Osler, St. Mary's; M. W. L. Owen, Camb. and St. Mary's; E. B. Pawson, Camb. and St. Bart.'s; G. E. Phillips, Cardiff; A. G. Potts, Guy's; F. J. P. Price, King's Coll.; G. A. Ransome, St. Bart.'s; H. G. Rees, Middlesex; T. G. Richards, Liverpool; A. E. G. Ridgway, London; T. J. Ryan, St. Bart.'s; H. B. C. Sandiford, St. Thomas's; R. D. Scriven, Westminster; F. W. Shepherd, Camb. and St. Bart.'s H. S. Shoham, Univ. College; J. P. Singer, Camb. and Guy's; F. J. Sladen, Middlesex; A. Smith, Leeds; B. W. Smith, Guy's; G. S. Steele-Perkins, Camb. and Guy's; M. Sternberg, Middlesex; J. N. Strauss, Manchester; Annie C. Taylor, Camb. and Univ. College; W. E. Thomas, Cardiff; A. S. Thorley, Univ. College; J. A. van Rooyen, St. Bart.'s; W. H. C. Watson, Camb. and St. Thomas's; W. H. Whiles, King's Coll.; F. C. H. White, Camb. and Birmingham; I. Whittington, St. George's; H. M. Williams, St. Bart.'s; G. Wilson, Guy's; J. I. Wilson, Univ. College; T. G. R. Woods, St. Bart.'s; H. W. Wykes, Middlesex; G. Zeidenfeld, St. Bart.'s.

Royal College of Surgeons of England.

A meeting of the Council of the Royal College of Surgeons was held on May 12th, with Lord Moynihan, the President, in the chair.

Diplomas of membership were granted to 154 of the 157 candidates whose names were given in our issue of May 7th as recipients of the L.R.C.P. (excepting S. N. Barker, A. L. Kenyon, and R. S. Sandhu), and also to F. H. Bentley, Manchester. A diploma in gynæcology and obstetrics was granted jointly with the Royal College of Physicians to D. P. de Villiers.

It was announced that the Lister medal for 1933 for distinguished contributions to surgical science had been awarded to Sir Charles Ballance, who will deliver the Lister memorial lecture at the College on some date in 1933.—It was reported that a bequest to the College by the late Mr. J. W. Groves had now become payable. The bequest is expected to amount to about £10,000, and the interest derived from it is intended for the purposes and objects of the museum, including the purchase of collections.

Diploma in Medical Radiology.

Regulations have just been instituted by the Royal College of Physicians of London and the Royal College of Surgeons of England for obtaining the diploma in Medical Radiology (D.M.R., R.C.P. & S. Eng.). The examination comprises: Part I.—Physics as applied to Radiology. Part II.—Medical Radiology, with special reference to its clinical application, including Radiodiagnosis. X Ray Therapy and Radium Therapy. Both parts will be held during the months of June and December. Eligible are candidates holding a qualification in medicine, surgery, and midwifery registrable in the British Register, or the M.D., or M.B., B.S. degrees of any University recognised by the examining board. The course of study extends over one academic year (nine months) of full-time study subsequent to the attainment of a recognised qualification. Appended to the regulations is a syllabus for Part I. No syllabus is issued for Part II. of the examination.

Royal College of Surgeons of Edinburgh.

At a meeting of the College on May 16th, with Mr. J. W. Dowden. the President, in the chair, the following 14 successful candidates (out of 82 entered) who passed the requisite examinations between Jan. 1st and 11th were admitted Fellows:—

Charles Bevan Carew Anderson, M.B. Edin.; Peter Melville Ballantyne, M.B. Toronto; John Bruce, M.B. Edin.; Santosh Kumar Chatterji, M.B. Calcutta; Daniel Peter de Villiers, M.B. Liverp.; David McKee Dickson, M.B. N.Z.; David Gamsu, M.D. Durh.; Edward Roger Graham Kirkpatrick, M.B. Sydney; Hyman Barnett Lieberman, M.B. Sydney; William Patrick, M.B. Glasg.; Lawrence Lees Playfair, M.D. Q.U. Ontario; George Largie Reid, M.B. Edin.; John Knox Stafford Thomson, M.B. Dub.; and Ronald Lister Verco, M.B. Adelaide.

The following candidates received the higher dental diploma:—

W. G. Middlemass, David Logie, G. B. Schofield, and C. L. Frizell.

The Liston Victoria jubilee prize, instituted in 1887 by Dr. Robert Halliday Gunning, and awarded triennially for the greatest benefit done to practical surgery by a Fellow or licentiate of the College, was awarded to Norman McOmish Dott, F.R.C.S. Edin.

Society of Medical Officers of Health.

Fever Hospitals Group.—The annual meeting of this group will be held at 1, Upper Montague-street, London, W.C., at 3.30 P.M. on Friday, May 27th, when Mr. W. H. Hobday, F.R.I.B.A., will read a paper on Isolation Hospital Construction.

Royal Northern Group of Hospitals.

A series of post-graduate lectures and demonstrations, to be given at the Royal Northern Hospital and the Royal Chest Hospital during the summer, begins next Monday with a week's "intensive" course. This will consist of two lectures each afternoon, with teaching in the wards and elsewhere at other times. A similar course will be held from June 13th to 17th. A full programme, including particulars of the ordinary weekly lectures on Tuesday or Wednesday afternoons, may be had from Dr. E. G. B. Calvert, dean of the hospital, Holloway-road, N. 7.

University of Oxford.

The Herbert Spencer lecture for 1932 will be given by Mr. R. A. Fisher, F.R.S., at the University Museum on June 8th. His subject is the Social Selection of Human Fertility.

Journées Médicales de Bruxelles.

This congress will hold its twelfth meeting from June 25th to 28th, under the presidency of Prof. Fernand Héger. The secretary-general is Dr. René Beckers, 141 rue Belliard, Brussels.

South-West London Medical Society.

Sir Humphry Rolleston will deliver the Bolingbroke lecture before this society at 9 P.M. on Wednesday, May 25th, at the Bolingbroke Hospital, Wandsworth Common. His subject will be the Advances in Medicine during the last Fifty Years.

Memorial to Dame Mary Scharlieb.

A ward will be dedicated and a tablet unveiled to the memory of Dame Mary Scharlieb, M.S., at the Royal Free Hospital at 4.45 P.M. on Tuesday, May 31st. The speakers will be Lady Barrett, Dr. Rosa Clark, and Dame Louise McIlroy; the ward will be dedicated by the Bishop of London; and the tablet will be unveiled by Lord Riddell, president of the hospital.

British Institute of Philosophy.

Sir Herbert Samuel, Secretary of State for Home Affairs, will deliver a presidential address, entitled Philosophy and the Ordinary Man, at 8.30 P.M. on Wednesday, May 25th, at University College, Gower-street, London, W.C. Tickets may be had from the Director of Studies, University Hall, 14, Gordon-square, W.C. 1.

Glasgow University Club, London.

The annual summer dinner of this club is to be held at the Café Royal, 68, Regent-street, W., at 7.15 for 7.30 P.M., on Friday, June 10th. The chair will be taken by the Very Reverend Sir George Adam Smith, principal of the University of Aberdeen. Any Glasgow University men who though not members of the club desire to attend are asked to communicate with the hon. secretaries, 62, Harley House, N.W. 1.

The Stamford Infirmary Difficulty.

Dr. G. Staveley Parker, who on March 30th last was dismissed from the staff of the Stamford and Rutland Infirmary for alleged breaches of the rules, and reinstated a fortnight later on a vote by a majority of the governors, has again been dismissed by a majority of 42 to 13. By the same resolution his partner, Dr. J. Purce, was appointed assistant surgeon. Dr. Purce has, however, declined the appointment.

Conference on Sterilisation.

As already announced, a Conference on Voluntary Eugenic Sterilisation will be held at the Caxton Hall, Westminster, on May 23rd under the auspices of the Eugenics Society. The speakers will include Sir Thomas Horder, Dr. R. Langdon-Down, Mr. C. J. Bond, Dr. C. P. Blacker, Lord Riddell, Mrs. C. B. S. Hodson, Prof. A. M. Carr-Saunders, and Prof. R. Ruggles-Coates, and in the evening, at 8.30, there will be a session at which members of the public may express their views and ask questions. The secretary's address is 16, Mulberry-walk, London, S.W. 3.

Society for Relief of Widows and Orphans of Medical Men.

At the annual general meeting, *held on May 11th*, Mr. V. Warren Low presiding, it was reported that the total membership of the society is 282, made up of 160 life members, 121 ordinary members, and one honorary member. On Dec. 31st, 1931, there were 49 widows and 6 orphans in receipt of grants. Five widows died during the year. One came on the fund in 1887 and received in grants £3300, another in 1917 and received £925, another in 1920 and received £750, another in 1922 and received £750, and the fifth, who came on the fund in 1926, received £450. The annual grant to widows over 65 years of age was £75, to those under 65, £60. Each orphan under 16 received £50. In addition a Christmas present of £15 was made to widows over 75 years of age, and £10 to each widow under that age. Each orphan received £10. The Copeland Fund is for orphans over the age of 16, who, owing to some permanent disablement, are prevented from earning a livelihood. The grant from this fund is £30 per annum. The sum of £389 8s. was also paid to eight orphans who had reached the age of 16, to enable them to continue their education at school or to start on some professional or business career. The grants are practically the same as last year. Invested funds remain the same—namely, £140,700. No legacies were received during the year.

Medical Diary

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, May 23rd.—8 P.M., ODONTOLOGY. Annual General Meeting at the Royal College of Surgeons, Lincoln's Inn Fields, W.C. Election of Officers and Council. Demonstration: Sir Frank Colyer will show new specimens received in the Museum during the past year.

TUESDAY.—5 P.M., MEDICINE. Election of Officers and Council. 8 P.M., [illegible] Discussion: So[illegible] and Treatment [illegible] Dr. W. R. F. [illegible] W. H. Bradley.

THURSDAY.—8.30 P.M., UROLOGY. Election of Officers and Council. Paper: Mr. H. P. Winsbury-White: Perinephric Inflammation.

FRIDAY.—DISEASE IN CHILDREN. No meeting. 8 P.M., EPIDEMIOLOGY AND STATE MEDICINE. Election of Officers and Council. Paper: Sir Aldo Castellani: The Epidemiology of Some Typical Mycoses.

SATURDAY.—12.30 P.M., PHYSICAL MEDICINE. The Annual Summer Meeting will take place at Alton. Special demonstrations of cases and appliances at the Treloar Cripples' Hospital.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.

FRIDAY, May 27th.—8.30 P.M., Dr. Otto May and Mr. H. E. Melville: The Attitude of Life Insurance Societies to Venereal Disease. A discussion will follow.

SOUTH-WEST LONDON MEDICAL SOCIETY.

WEDNESDAY, May 25th.—[illegible] Hospital, Bolingbroke-grove, [illegible] Sir Humphry Rolleston: [illegible] During the Last Fifty Years. (Bolingbroke lecture.)

MEDICO-LEGAL SOCIETY.

THURSDAY, May 26th.—8.30 P.M. (at 11, Chandos-street, Cavendish-square, W.), Colonel L. W. Harrison: The Medico-legal Aspects of Venereal Disease, followed by *a discussion.*

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, May 23rd, to SATURDAY, May 28th.—LONDON [illegible] S.W. LIGHT AND ELECTRICAL C[illegible] An evening course in Ph[illegible] Wed. from 8 to 9 P.M. [illegible] CLINICAL PATHOLO[illegible] Epidiascope and [illegible] Knyvett Gordon on [illegible] —ST. JOHN'S HOSPITAL, Leicester-square, W.C. Afternoon course in Dermatology. Clinical work at 2 P.M. and 6 P.M. daily. Lectures on Mond., Tues., Thurs., and Frid. at 5 P.M.—PRINCE OF WALES'S HOSPITAL, Tottenham, N.15. All-day course in Medicine, Surgery, and the Specialties. 10.30 to 4.30 P.M. daily. Operations, special demonstrations, lectures.—(The above courses are open only to Members of the Fellowship of Medicine.)

CHADWICK TRUST.

MONDAY, May 23rd.—5.15 P.M. (at the House of the Royal Society of Arts, John-street, Adelphi), Sir Ernest Graham-Little: Dermatology as an Outpost of Medicine (Malcolm Morris lecture).

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

(Intensive Course.)

MONDAY, May 23rd.—2.15 P.M., Mr. F. D. Saner: Selected Cases. 3.15 P.M., Mr. C. S. Lane Roberts: Some Drugs in Pregnancy and Labour.

TUESDAY.—2.15 P.M., Dr. E. G. B. Calvert: Recent Work on the Anæmias: Ætiology and Treatment. 3.15 P.M., Mr. Kenneth Walker: Renal Pain.

WEDNESDAY.—2.15 P.M., Dr. Bernard Schlesinger: Demonstration of Cases in the Children's Ward. 3.15 P.M., Dr. H. C. Semon: Case Demonstration.

THURSDAY.—2.15 P.M., Mr. Eric Lloyd: Bone Setting. 3.15 P.M., Mr. E. Wolff: Ocular Headache.

FRIDAY.—2.15 P.M., Dr. Claude Gouldesbrough: Fractures and Dislocations (continued). 3.15 P.M., Dr. P. O. Ellison and Dr. Sholto McKenzie: Pathological Investigations.

NATIONAL HOSPITAL, Queen-square, London, W.C.

MONDAY, May 23rd.—2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Kinnier Wilson: The Borderland of Epilepsy.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Martin: [illegible]

WEDNESDAY.—2 P.M., Dr. [illegible]

THURSDAY.—2 P.M., Dr. Kin[illegible] 3.30 P.M., Dr. Critchley: Electrical Injuries of the Nervous System.

FRIDAY.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. Walshe: Muscular Atrophy.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, May 27th.—4 P.M., Mr. H. Kisch: Nasal Obstruction.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION; St. James's Hospital, Ouseley-road, Balham, S.W.

WEDNESDAY, May 25th.—4 P.M., Mr. G. Perkins: Modern Tendencies in the Treatment of Non-pulmonary Tuberculosis.

ST. PAUL'S HOSPITAL, Endell-street, W.C.
WEDNESDAY, May 25th.—Dr. G. R. M. Cordiner: Urinary Symptoms. Radiological Interpretation.

ST. MARK'S HOSPITAL, City-road, E.C.
THURSDAY, May 26th.—4.30 P.M., Sir Charles Gordon-Watson: Diagnosis and Treatment of Carcinoma of the Colon.

ST. PETER'S HOSPITAL, Henrietta-street, Covent Garden, W.C.
WEDNESDAY, May 25th.—3 P.M., Mr. J. Swift Joly: Operation of Prostatectomy.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.
WEDNESDAY, May 25th.—5 P.M. (at St. John's Hospital, 49, Leicester-square, W.C.), Clinical Cases.

LONDON JEWISH HOSPITAL, Stepney Green, E
THURSDAY, May 26th.—4.15 P.M., Dr. David Krestin: Demonstration of Cases.

NATIONAL CENTRE AND POST-GRADUATE SCHOOL OF RADIOTHERAPY, Riding House-street, W.
WEDNESDAY, May 25th.—4.30 P.M., Mr. Ogier Ward: Bladder and Prostate.

ROYAL INSTITUTION, Albemarle-street, W.
FRIDAY, May 27th.—9 P.M., Sir Walter Morley Fletcher: New Conceptions of Medical Research.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.
MONDAY, May 23rd.—5 P.M., Dr. H. Haldin-Davis Drug Eruptions.
TUESDAY.—5 P.M., Dr. J. E. M. Wigley: Napkin Area Eruptions.
THURSDAY.—5 P.M., Dr. A. M. H. Gray: Sclerema.
FRIDAY.—5 P.M., Dr. W. J. O'Donovan: Tuberculosis of the Skin.

UNIVERSITY OF BIRMINGHAM.
WEDNESDAY, May 25th.—4 P.M., Mr. C. J. Bond: Some Aspects of Human Biology. (Last William Withering Memorial Lecture.)

EYE INFIRMARY, Glasgow.
WEDNESDAY, May 25th.—4.15 P.M., Dr. A. J. Ballantyne and Dr. S. S. Meighan: Eye Cases.

Appointments

ELKINGTON, J. ST. C., M.B., B.Chir. Camb., M.R.C.P. Lond., has been appointed Physician to Out-patients, St. Thomas's Hospital.

RUSHWORTH, J. A., L.R.C.P. Lond., M.R.C.S., Assistant Tuberculosis Officer, Liverpool Health Department.

SIMPSON, N. C., M.D., Ch.B. Aberd., Certifying Surgeon under the Factory and Workshop Acts, Newmarket District.

WARBURTON, P. D., L.R.C.P. Lond., M.R.C.S., D.P.H., Honorary Surgeon, West of England Eye Infirmary, Exeter.

Vacancies

For further information refer to the advertisement columns.

Altrincham General Hospital.—Sen. and Jun. H.S. At rate of £150 and £120 respectively.

Banbury, Oxon, Horton General Hospital.—Res. M.O. At rate of £150.

Bedford County Hospital.—Second H.S. At rate of £140.

Benenden, Kent National Sanatorium.—Res. Asst. M.O. £300.

Birkenhead General Hospital.—Hon. Asst. Surgeon.

Birmingham and Midland Eye Hospital, Church-street.—H.S. £110.

Bradford, Royal Eye and Ear Hospital.—Jun. H.S. £150

Bristol, City and County of.—Asst. M.O.H. £500.

Bristol General Hospital.—Hon. Obstet. Phys. and Gynæcologist, Hon. Asst. Obstet. Phys. and Gynæcologist; also Hon. Surg. and Hon. Asst. Surg.

Burnley, Victoria Hospital.—H.P. At rate of £150.

Camberwell House, London, S.E.—Third Asst. M.O. £300.

Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.

Carlisle. Cumberland Infirmary.—Second H.S. £155.

Chelsea Hospital for Women, Arthur-street, S.W.—Jun. H.S. At rate of £100.

Chesterfield and North Derbyshire Royal Hospital.—H.S. £150.

City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.

Colchester, Essex County Hospital.—Asst. H.S. £120.

Coventry and Warwickshire Hospital.—Res. Cas. O. £125.

Derby, Derbyshire Royal Infirmary.—H.S. for General Surgery. £150.

Dewsbury and District General Infirmary.—Second H.S. £150.

Doncaster Royal Infirmary.—H.S. and Cas. H.S. Each at rate of £175.

Durham County Council.—Asst. Welfare M.O. £500.

Durham University College of Medicine, Newcastle-upon-Tyne.—Professorship of Bacteriology. £1000.

East Ham County Borough.—Asst. M.O. £500.

East Ham Memorial Hospital, Shrewsbury-road, E.—Res. M.O. At rate of £200.

Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—H.P., Obstetric Asst. Also three H.S.'s. Each at rate of £50.

Galway, University College.—Professorship of Medicine. £336–£350.

General Lying-in Hospital, York-road, Lambeth, S.E.—Jun. Res. M.O. and Anæsthetist. At rate of £100.

Glasgow, West of Scotland Neuro-Psychiatric Research Institute.—Director. £850.

Gloucester. Gloucestershire Royal Infirmary, &c.—Asst. Surgeon.

Golden-square Throat, Nose, and Ear Hospital, W.—H.S. £100.

Halifax, St. Luke's Hospital.—Jun. Res. M.O. £250.

Hospital for Sick Children, Great Ormond-street, W.C.—Part-time Jun. Cas. O. At rate of £150. Also H.P. and H.S. Each at rate of £100.

Ilford, King George Hospital.—H.S. At rate of £100.

Indian State Railways.—District M.O. Rs.650 per mensem.

Ipswich, East Suffolk and Ipswich Hospital.—H.S. £120. Also Res. M.O. £350.

Kingston-upon-Hull, Hull Municipal Maternity Home and Infants Hospital.—Jun. Res. M.O. At rate of £100.

Liphook, Hants, King George's Sanatorium for Sailors.—Asst. M.O. At rate of £200.

L.C.C.—Temporary Asst. Organisers. 66*s.* 6*d.* each a week.

L.C.C. District 11, Area IX., Deptford.—Temp. District M.O. £210.

London Jewish Hospital, Stepney Green. E.—Clin. Asst.

Manchester.—Asst. M.O. for Crossley Sanatorium, Delamere Forest, Cheshire. £200.

Manchester and District Radium Institute.—Asst. M.O. £500. Also Clin. Asst. £250.

Manchester Hospital for Consumption and Diseases of the Throat and Chest.—Hon. Physician.

Middlesex County Council.—Dist. M.O. for Harmondsworth &c.—£97–£100. Also Public Vaccinator.

Miller General Hospital, Greenwich-road, S.E.—Cas. O. At rate of £150. Also H.S. and H.P. Each at rate of £100.

National Hospital, Queen-square, W.C.—Asst. Pathologist. £250.

Newark General Hospital.—Res. H.S. £175.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Med. Regs. Each £250.

Nottingham General Hospital.—Res. Cas. O. At rate of £200.

Oldham Royal Infirmary.—H.S. At rate of £175.

Plymouth Central Hospital.—Res. H.S. At rate of £150.

Princess Louise Kensington Hospital for Children, St. Quentin-avenue, North Kensington, W.—H.S. At rate of £75.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Asst. Res. M.O. At rate of £80.

Queen Mary's Hospital for the East End, E.—Res. M.O. At rate of £200. Also Cas. O., H.P.'s and H.S.'s. At rate of £150 and £120 respectively.

Richmond Borough (Surrey).—M.O. to Antenatal Clinic. £1 11*s.* 6*d.* per session.

Royal Chest Hospital, City-road, E.C.—Med. Regs. £50.

Royal Free Hospital, Gray's Inn-road, W.C.—Cas. O. At rate of £150. Also H.S.'s, H.P.'s, &c. All at rate of £100. Also H.P. to Children's Dept.

Royal London Ophthalmic Hospital, City-road, E.C.—Five Out-Patients Officers. Each £100.

Salford, City.—Jun. Asst. for Venereal Diseases Treatment Centre. At rate of £500.

St. John's Hospital for Diseases of the Skin, 49, Leicester-square W.C.—In-patient Med. Reg. £50.

St. Mark's Hospital for Cancer, &c., City-road, E.C.—Res. Surg. O. At rate of £150.

St. Stephen's Hospital, Fulham-road, S.W.—Clin. Asst. At rate of £100.

St. Thomas's Hospital.—Physician for Skin Dept.

Samaritan Free Hospital for Women, Marylebone-road.—Hon. Surg. to Out-patients.

Truro, Royal Cornwall Infirmary.—H.S. £170.

University College Hospital, Gower-street, W.C.—Hon. Asst. P.

Victoria Hospital for Children, Tite-street, Chelsea, S.W.—Surg to Ear, Nose, and Throat Dept.

Warrington Infirmary and Dispensary.—Jun. H.S. £175.

West End Hospital for Nervous Diseases, Welbeck-street, W.—Hon. Anæsthetist.

Weston-super-Mare, General Hospital.—Res. H.S. £150.

Willesden General Hospital, N.W.—Clin. Assts. for Out-patient Department.

Wolverhampton Royal Hospital.—H.S. At rate of £100.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Middleton (Lancaster); Talybont (Cardigan); and at Droitwich (Worcester).

Births, Marriages, and Deaths

BIRTHS.

FARQUHARSON.—On May 11th, at Breda, Severn-avenue, Weston-super-Mare, the wife of Dr. J. L. Farquharson, of a daughter.

LYONS.—On May 15th, at 12, The Avenue, Lincoln, to Dorothy, the wife of J. Lyons, M.D., F.R.C.S.—a daughter.

WARD.—On May 10th, at Deepdene, Cheadle Hulme, Cheshire, the wife of John Forbes Ward, M.D., of a daughter.

MARRIAGES.

SELLORS—CHESSHIRE.—On May 11th, in London, Thomas Holmes Sellors, M.Ch., F.R.C.S., of Gordon-mansions, Francis-street, W.C., to Dorothy Elizabeth, eldest daughter of Mr. and Mrs. John Chesshire, formerly of Worcestershire.

DEATHS.

BLACKBURN.—On May 11th, William Howard Blackburn, M.A., M.B., B.Ch., D.P.H., M.R.C.S., M.O.H.

HULL.—On May 12th, as the result of an accident, at Beaufort Lodge, Streatham Common, Edward Gordon Hull, M.A., M.D., D.S.M.

PAXON.—On May 7th, at Eastern Fever Hospital, Homerton, Valentine Preston Paxon, B.A., B.Ch., aged 28.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

THE VIRUS OF POLIOMYELITIS.

A LEADING article in our issue of April 16th summarised some recent advances in the identification of filtrable viruses with elementary bodies visible under the microscope. Work along these lines has lately given fairly definite results in relation to poliomyelitis, and goes far to confirm the findings of Flexner and Noguchi 20 years ago. From cases of poliomyelitis these investigators grew cultures of what they described as "globoid bodies." Since then, however, similar appearances have been described in several different diseases and some of them have been shown to be artefacts. The importance of Flexner and Noguchi's observations has therefore been doubted, but they are brought back into prominence by the experiments of P. H. Long, P. K. Olitsky, and C. P. Rhoads[1] at the Rockefeller Institute, New York.

The globoid bodies were described by Noguchi and Flexner as minute formed structures cultivated either from unfiltered emulsions of the nervous tissues or from the filtrate after passage through a Berkefeld candle.

The culture medium consisted essentially of human ascitic fluid to which had been added a fragment of sterile, fresh tissue, usually rabbit's kidney. The liquid was covered with a deep layer of sterile paraffin and incubated at 37° C. After five days an opalescence appeared about the fragments of tissue and after a further three to five days it extended into the upper portion of the medium. After 10 to 12 days the haziness began to diminish and irregular particles were *formed which slowly fell to the bottom of the tube.*

To demonstrate colony formation by the "bodies" a semi-solid medium was used, consisting of ascitic fluid and kidney with sufficient 2 per cent. agar to produce a solid mixture. This medium was not successful for initial growths, but transfer could be effected to it after about the third generation of growth in the fluid medium. In this medium minute colonies formed about the tissue fragments. It was shown that neither the ascitic fluid nor the kidney was essential for the formation of globoid bodies, and although media from which both of these tissues were absent were inferior to the mixtures containing them, it was apparent that the growth was not derived from the kidney tissue or ascitic fluid, but primarily from the inoculum.

The globoid bodies were minute globular structures 0·15–0·3μ in diameter and arranged in pairs, chains, *or small masses according to the nature of the medium* ; in earlier generations the bodies stained feebly with Gram's stain, but in other cultures more intensely. It seemed that considering their property of forming definite colonies and their distinctive morphology these bodies were entitled to be regarded as organisms.

Flexner and Noguchi found that only exceptional cultures were pathogenic when injected intracerebrally into monkeys.

Two sets of inoculation experiments were, however, reported, one with globoid bodies derived from human cases, and the other with those derived from the M.A. virus already propagated in a long series of monkeys. With the human strain the third sub-plant (third generation) of the "organisms" proved fatal to monkeys ; the animals developed poliomyelitis and from their nervous systems globoid bodies were in turn cultivated. With the monkey strain the third, fifth, and sixth generations produced positive results. In addition, a monkey was inoculated with a mixed culture representing the eighteenth and twentieth generations and, although it died from an intercurrent infection, from its central nervous system, after death a filtrate was obtained which gave rise to typical experimental poliomyelitis in another monkey.

Subsequently, Flexner, Noguchi, and Amoss obtained what they regarded as "mass" cultures of globoid bodies and proved that they were infective and that globoid bodies could be cultivated again from the nervous system of the animals dying of poliomyelitis after the inoculation. It was shown that globoid bodies kept in the semi-solid medium at room temperature were still pathogenic for the monkey 19 months after their isolation. In the ice-box too, as Amoss afterwards showed, they could survive several months. Strict anaerobiosis was *essential.*

Long, Olitsky, and Rhoads, in their repetition of this work, inoculated about 50 tubes of medium during each attempt at cultivation. They used virus from the brains of seven monkeys. After 10 to 14 days each tube was examined ; any that showed contamination with known bacteria was discarded, any that showed material resembling globoid bodies was sub-planted to six or eight tubes of Noguchi's fluid medium. Controls were kept at all stages. The opalescence described by Flexner and Noguchi was not detected, but out of 31 [illegible] 36 showed minute bodies [illegible] such apparent growths were obtained from all seven monkeys, but those from three failed after the first sub-planting ; the others showed successive "growths" up to the third, fourth, eighth, and eleventh sub-planting, respectively.

In early sub-plants the bodies were single, in pairs, or in short chains, and the individual bodies had a fairly uniform appearance. In older sub-plants the bodies were more numerous and in part formed agglomerated masses. They stained well with alkaline methylene-blue, but not, as a rule, with Gram's stain. It is important to note that in almost all film preparations from sub-plants kidney tissue-cells and leucocytes were observed.

The cultures of the successive sub-plants were pathogenic for monkeys ; the animals developed typical experimental poliomyelitis and after their death, inoculation of material from their nervous systems into other monkeys reproduced the disease. Furthermore, in every case except one, globoid bodies were again cultivated from the nervous tissues of the monkeys after death. Such results were obtained with the sixth, seventh, eighth, ninth, and tenth sub-plants from one of the original cultures. The seventh transfer represents a dilution of the original material of about $1{\cdot}5 \times 10^{12}$ and the tenth of about $1{\cdot}3 \times 10^{13}$. Flexner and Noguchi had calculated that without reproduction of the virus by growth, the limit beyond which the mixture would not be infective was represented by the second transfer of the original virus in the culture medium.

It was found that tubes which did not show the appearance of "globoid bodies" were not infective. Thus, material from four such tubes of the ninth transfer, and again from five such tubes of the tenth transfer failed to produce any disease when inoculated into monkeys in the usual way, although as has been said, "positive" tubes of the same *generation had been found to* be actively pathogenic.

As regards colony growth, Flexner and Noguchi's special semi-solid medium was not used. but on rabbit-blood-dextrose-agar plates incubated anaerobically, no colonies were detected. "Mass" cultivation was also unsuccessful.

From their study of these minute bodies Long, Olitsky, and Rhoads were not convinced that they were dealing with cultures of the actual "globoid bodies" or indeed of any living micro-organism. Nevertheless, the inoculation experiments left no doubt that the poliomyelitic virus had multiplied in the culture tubes and they believe that it increased as a consequence of being in a medium of modified tissue-cell culture ; for in almost all specimens many well-preserved kidney tissue-cells and leucocytes were observed, the latter being probably derived from the ascitic fluid. Since only those tubes which showed the appearance of globoid bodies were infective, it may be that the virus is adsorbed to these bodies : but no suggestion is offered as to the derivation of the globoid bodies themselves.

Since the publication of this work it has been announced (*Times*, Jan. 2nd, 1932) that Prof. F. Eberson, of San Francisco, has succeeded in isolating the causal organism of poliomyelitis, which is stated to become visible only after several weeks' cultivation.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.—Special post-graduate facilities are offered at the Royal Maternity and Women's Hospital during August and September. Particulars may be had from the house superintendent of the hospital, Rottenrow, Glasgow.

A SUPRAPUBIC CATHETER AND ITS MANAGEMENT.

In 1923 a business man, aged 69, underwent prapubic cystotomy because of simple enlargement f the prostate. Thereafter, until his death in March, 931, urine was passed solely through the cystotomy pening, and a number of methods were used to ecure comfort and freedom from leakage.

His widow informs us that for the first 15 months fter the operation success in these objects was not ttained, although no limit was put to expenditure r scope of inquiry. Self-retaining catheters, it was ound, were apt to give pain in insertion and withrawal, and they "may cause serious trouble if mportant parts of the head perish and give way. traight catheters are liable to leak, and rarely proved eliable for all positions of the body." Progressive ncrease in their size proved necessary, and their use vas therefore abandoned.

Numerous firms were consulted and offered ingenious levices for absorbing, detaining, or directing leakage as it occurred. It was felt, however, that the leakage must be stopped at the bladder end of the sinus, and this led the patient's wife to devise the method described below.

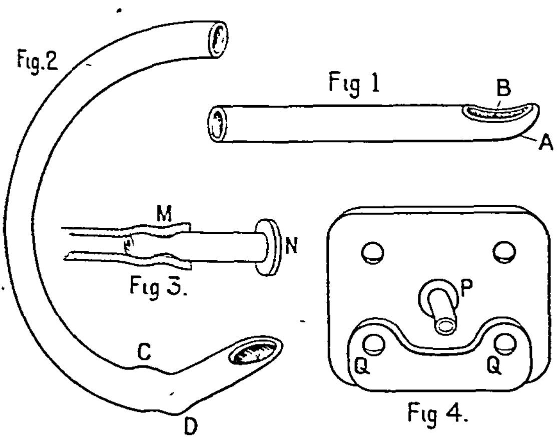

FIG. 1.—Termination of a straight catheter, showing spoon-shaped outer surface and long aperture ($\frac{5}{8}$ in.).
FIG. 2.—Catheter prepared for use, showing curve and bulges. C, Decided bulge on inner side of curve. D, Slight bulge on outer side of curve.
FIG. 3.—Hollow bottle-shaped glass stopper: M, open end entering catheter; N, closed end.
FIG. 4.—Bone gadget laid over lower part of rubber shield, shaped bone 1/16 in. thick, with two holes fitting over studs at Q. P is place of emergence of catheter.

During 1925 and 1926, after its adoption, the patient missed only two days at business, living an ordinary active life from 10.30 A.M. to 9.15 P.M., and usually required no nursing attention during the day. No extra bed-linen or personal garments were needed. He was very well, put on weight, and was able to walk one and a half miles quite easily until late in 1929. On one occasion in 1926 he travelled from King's Cross to Leeds, inspected a large factory, and returned on the same day without undue fatigue. In January, 1928, there was serious leakage, but the same method was pursued successfully after advancing to catheter No. 23.

From this time on the method was not uniformly successful: there were occasional leakages. The patient was now very gradually losing ground, and the diminution of bladder capacity caused difficulty. Still success was often attained for weeks and months at a time, and extra bed-linen was rarely required until 1930. The patient was able to enjoy life, and spent several hours a day at business up to the end of 1929. In the last two months of his life there was leakage about one-third of the time, but the method was still largely successful. Dr. E. Collingwood Andrews states that until the last few weeks the urine remained acid and free from pus.

The apparatus used has the following features as stated by the designer:—

Special shaped ends.—Many straight catheters with side apertures have much superfluous rubber on the ends beyond the aperture. To avoid this spoon-shaped ends with slightly longer apertures were employed (Fig. 1). This made a great deal of difference to the patient's comfort, and lessened the likelihood of internal contact. As a result there was usually no trace of blood in the urine.

Elimination of leakage.—The straight catheter is a cylindrical body passing in use through an approximately cylindrical passage. Any straight cross-section of a cylinder is a circle, any slanting cross-section is an ellipse of greater area than the circle; therefore, if a cylindrical catheter be curved or bent and adjusted so that an elliptical cross-section occupies the bladder end of the sinus, leakage can be prevented. In the course of a handicraft method of curving the catheters certain bulges appeared incidentally which assisted to stop leakage. The curved catheter is illustrated in Fig. 2.

Device for adjustment.—It was found in practice that there was still a slight occasional oozing from the lower side of the circle of emergence of the catheter, due to some wobbling. This was corrected by strongly reinforcing the rubber tube part of the shield containing the catheter, and more especially by introducing a shaped bone gadget 1/16 in. thick laid on the lower part of the shield, as shown in Fig. 4. With these arrangements the patient was able to wear the same gauze dressings for 48 hours. The catheter was usually kept in for a fortnight, being changed in a regular routine every other Saturday night. Occasionally a very comfortable one was used a few days longer.

Leakage at special times.—Still there might be leakage at a bath time or any short period when the catheter was clipped up and the urinary bottle had been removed. Fig. 3 shows a device to prevent this, a hollow glass stopper placed in the catheter; the patient can see when it fills and evacuate, so that this type of leakage is not permitted. Analogous to this, not illustrated, is the suggestion of an extremely light temporary bottle, capacity half a pint only, for direct application to the catheter, for use in the late stages when the patient is often out of bed restlessly for short intervals. Another device which should be very useful in nursing these cases is a frictionised, powerfully elastic, ring-shaped band to secure the catheter at the outside point of entry to the rubber shield; this makes readjustments much easier and quicker than when sticky plaster is used.

NORWOOD SANATORIUM, LIMITED.

THE twenty-fifth report of the Rendlesham and Beckenham Branches of the Norwood Sanatorium opens with statistics showing that deductions are made upon a large basis. Over 7000 patients, being an average of 280 a year, are passed under review, 5983 males and 1061 females, the ages of the males varying from 20 to 72 and of the females from 25 to 76 years. Of these cases 1904 appeared to have an alcoholic heredity, 992 from paternal sources, 314 from maternal sources, and 898 from both parents. The patients have all belonged to the relatively upper strata of society in which, it would seem, the predisposition to indulgence may be definitely inherited, but in this connexion a comment, in the paragraph describing the occupation of the patients, is to the point. For it stands out clearly that those patients with little or no occupation, whatever their social status, are apt to fall victims of the habit. In women of all classes menstrual troubles, particularly dysmenorrhœa and depression associated with menopause are found definitely to lead to alcoholism. Commenting on the causation of other drug habits we have the satisfactory assertion that the operations of the Dangerous Drugs Acts have had a remarkable result in diminishing the number of cases of patients who have become addicts. The report closes with the satisfactory statement from the medical superintendents, that investigations are in progress to determine the fasting blood-sugar value in persons who have a craving for alcohol.

NOTES, COMMENTS, AND ABSTRACTS

THE VIRUS OF POLIOMYELITIS.

A LEADING article in our issue of April 16th summarised some recent advances in the identification of filtrable viruses with elementary bodies visible under the microscope. Work along these lines has lately given fairly definite results in relation to poliomyelitis, and goes far to confirm the findings of Flexner and Noguchi 20 years ago. From cases of poliomyelitis these investigators grew cultures of what they described as "globoid bodies." Since then, however, similar appearances have been described in several different diseases and some of them have been shown to be artefacts. The importance of Flexner and Noguchi's observations has therefore been doubted, but they are brought back into prominence by the experiments of P. H. Long, P. K. Olitsky, and C. P. Rhoads [1] at the Rockefeller Institute, New York.

The globoid bodies were described by Noguchi and Flexner as minute formed structures cultivated either from unfiltered emulsions of the nervous tissues or from the filtrate after passage through a Berkefeld candle.

The culture medium consisted essentially of human ascitic fluid to which had been added a fragment of sterile, fresh tissue, usually rabbit's kidney. The liquid was covered with a deep layer of sterile paraffin and incubated at 37° C. After five days an opalescence appeared about the fragments of tissue and after a further three to five days it extended into the upper portion of the medium. After 10 to 12 days the haziness began to diminish and irregular particles were formed which slowly fell to the bottom of the tube.

To demonstrate colony formation by the "bodies" a semi-solid medium was used, consisting of ascitic fluid and kidney with sufficient 2 per cent. agar to produce a solid mixture. This medium was not successful for initial growths, but transfer could be effected to it after about the third generation of growth in the fluid medium. In this medium minute colonies formed about the tissue fragments. It was shown that neither the ascitic fluid nor the kidney was essential for the formation of globoid bodies, and although media from which both of these tissues were absent were inferior to the mixtures containing them, it was apparent that the growth was not derived from the kidney tissue or ascitic fluid, but primarily from the inoculum.

The globoid bodies were minute globular structures $0{\cdot}15$–$0{\cdot}3\,\mu$ in diameter and arranged in pairs, chains, or small masses according to the nature of the medium; in earlier generations the bodies stained feebly with Gram's stain, but in other cultures more intensely. It seemed that considering their property of forming definite colonies and their distinctive morphology these bodies were entitled to be regarded as organisms.

Flexner and Noguchi found that only exceptional cultures were pathogenic when injected intracerebrally into monkeys.

Two sets of inoculation experiments were, however, reported, one with globoid bodies derived from human cases, and the other with those derived from the M.A. virus already propagated in a long series of monkeys. With the human strain the third sub-plant (third generation) of the "organisms" proved fatal to monkeys; the animals developed poliomyelitis and from their nervous systems globoid bodies were in turn cultivated. With the monkey strain the third, fifth, and sixth generations produced positive results. [illegible] inoculated with a mixed culture [illegible] and twentieth generations an[illegible] an intercurrent infection, from its central nervous system, after death a filtrate was obtained which gave rise to typical experimental poliomyelitis in another monkey.

Subsequently, Flexner, Noguchi, and Amoss obtained what they regarded as "mass" cultures of globoid bodies and proved that they were infective and that globoid bodies could be cultivated again from the nervous system of the animals dying of poliomyelitis after the inoculation. It was shown that globoid bodies kept in the semi-solid medium at room temperature were still pathogenic for the monkey 19 months after their isolation. In the ice-box too, as Amoss afterwards showed, they could survive several months. Strict anaerobiosis was essential.

Long, Olitsky, and Rhoads, in their repetition of this work, inoculated about 50 tubes of medium during each attempt at cultivation. They used virus from the brains of seven monkeys. After 10 to 14 days each tube was examined; any that showed contamination with known bacteria was discarded, any that showed material resembling globoid bodies was sub-planted to six or eight tubes of Noguchi's fluid medium. Controls were kept at all stages. The opalescence described by Flexner and Noguchi was not detected, but out of 315 tubes originally inoculated, 30 showed minute bodies suggesting micro-organisms; such apparent growths were obtained from all seven monkeys, but those from three failed after the first sub-planting; the others showed successive "growths" up to the third, fourth, eighth, and eleventh sub-planting, respectively.

In early sub-plants the bodies were single, in pairs, or in short chains, and the individual bodies had a fairly uniform appearance. In older sub-plants the bodies were more numerous and in part formed agglomerated masses. They stained well with alkaline methylene-blue, but not, as a rule, with Gram's stain. It is important to note that in almost all film preparations from sub-plants kidney tissue-cells and leucocytes were observed.

The cultures of the successive sub-plants were pathogenic for monkeys; the animals developed typical experimental poliomyelitis and after their death, inoculation of material from their nervous systems into other monkeys reproduced the disease. Furthermore, in every [illegible] were again cultivated from the [illegible] after death. Such results we[illegible] seventh, eighth, ninth, and tenth sub-plants from one of the original cultures. The seventh transfer represents a dilution of the original material of about $1{\cdot}5 \times 10^{12}$ and the tenth of about $1{\cdot}3 \times 10^{13}$. Flexner and Noguchi had calculated that without reproduction of the virus by growth, the limit beyond which the mixture would not be infective was represented by the second transfer of the original virus in the culture medium.

It was found that tubes which did not show the appearance of "globoid bodies" were not infective. Thus, material from four such tubes of the ninth transfer, and again from five such tubes of the tenth transfer failed to produce any disease when inoculated into monkeys in the usual way, although as has been said, "positive" tubes of the same generation had been found to be actively pathogenic.

As regards colony growth, Flexner and Noguchi's special semi-solid medium was not used, but on rabbit-blood-dextrose-agar plates incubated anaerobically, no colonies were detected. "Mass" cultivation was also unsuccessful.

From their study of these minute bodies Long, Olitsky, and Rhoads were not convinced that they were dealing with cultures of the actual "globoid bodies" or indeed of any living micro-organism. Nevertheless, the inoculation experiments left no doubt that the poliomyelitic virus had multiplied in the culture tubes and they believe that it increased as a consequence of being in a medium of modified tissue-cell culture; for in almost all specimens many well-preserved kidney tissue-cells and leucocytes were observed, the latter being probably derived from the ascitic fluid. Since only those tubes which showed the appearance of globoid bodies were infective, it may be that the virus is adsorbed to these bodies; but no suggestion is offered as to the derivation of the globoid bodies themselves.

Since the publication of this work it has been announced (*Times*, Jan. 2nd, 1932) that Prof. F. Eberson, of San Francisco, has succeeded in isolating the causal organism of poliomyelitis, which is stated to become visible only after several weeks' cultivation.

BRIGHT'S DISEASE.

E UNITY AND RELATIONSHIPS OF TOXIC NEPHRITIS.

BY HUGH GAINSBOROUGH, M.D. CAMB.,
F.R.C.P. LOND.,
PHYSICIAN TO ST. GEORGE'S HOSPITAL.

RECENTLY much attention has been given to the assification of Bright's disease, with some tendency an increasing subdivision thereof. Further, a rticular dispute has arisen as regards the relation- ip of nephrosis and nephritis. One recent classi- ation presents an entirely new nomenclature). Russell[1]).

Some degree of clarity has emerged, as for example e abolition of such a name as chronic interstitial ephritis, and descriptions of nephritis by the colour nd size of the kidney. New classifications have een based on either the histological picture (Russell) r on this in correlation with the main clinical features Addis[2]). The use of old and new classifications t the same time is confusing, and their multiplicity uggests that they are not yet based on sound natural ivisions, if indeed such exist. In all schemes there re no definite borderlines between the divisions, hich hence are grouped arbitrarily in such a way s to accentuate certain main differences, just as he solar spectrum is divided into groups of wave- engths corresponding to our main visual perceptions f colour but without acknowledgment of the gradual transition of wave-length. Some classification of Bright's disease is essential for the convenience of the observer and for descriptive purposes, for the determination of the appropriate therapy, and for the acquisition of knowledge of ætiology, pathogeny, and particularly of prognosis.

So far no scheme is entirely satisfactory when considered from all points of view, and this is perhaps not surprising. Histological examination, however well correlated with the clinical standpoint, must rely on those cases which die; but death is not, as it were, evenly distributed among the so-called "types" of the disease, nor is it easy to build up a composite histological picture of the changes which occur in one case from material obtained from different cases at different stages. Even if this difficulty were overcome there are still other troubles in comparing clinical aspects—two cases might present histological features that are very similar, yet in one massive œdema is present, in the other absent. The clinical aspect is further confused by the reliance on so-called tests of renal function which are generally too coarse. A petrol engine may fail to yield its full power for many reasons, there may be increased friction in many parts, or the damage might be in one place, nevertheless the effects of diverse "lesions" on power output might be the same. Addis[3] introduced a method of estimating the amount of reduction of renal tissue, but identical degrees of reduction can be produced by various lesions, and advanced chronic patchy inflammation may reduce the renal capacity as much as an acute diffuse affection. Other methods of estimating renal function—as for example the estimation of blood-urea—are still less adequate, for increase of blood-urea only occurs when the "renal tissue" is reduced by at least 50 per cent.[4] Thus urea retention provides a very arbitrary standard for the comparison of cases of nephritis. Loss of renal function cannot yet be correlated with the histological appearances, the effects on renal excretory capacity of reversible or irreversible changes cannot be estimated, glomeruli normal or almost normal to the eye may yet be leaky filters, as indeed they must be in "genuine" nephrosis.

Addis and Oliver[2] in a remarkable work have simplified the classification of Bright's disease. Their scheme, which corresponds in many ways to the more subdivided one proposed by Russell, is based on clinical and histological studies of fatal cases, the clinical study by the methods developed by Addis being of special interest. Although the main groups are well distinguished, there is still the limitation of a method dependent on post-mortem material, and such groups seem less well defined when the disease is considered in all the aspects of all the cases which are presented to the clinician.

For the starting point of this discussion, the following scheme corresponds to many classifications. Any term belonging to old nomenclature, such as "small white kidney," will only be used in a rough sense sanctioned by long clinical usage.

(1) *Toxic Nephritis.*
  Acute: (*a*) Focal (non-embolic). (*b*) Diffuse.
  Subacute: } Glomerulo-nephritis. Glomerulo-tubular nephritis.
  Chronic: } Large and small white kidney.
(2) *Nephrosis.*
  "Genuine" or "lipoid" nephrosis.
(3) *Arterio-sclerotic.*
  (*a*) Senile (benign nephro-sclerosis). (*b*) Primary contracted kidney (malignant nephro-sclerosis).

The last group will not be discussed in this paper.

The groupings of "toxic" nephritis are rough divisions based on the acuteness or otherwise of the disease process, and it is often difficult to know into which of neighbouring categories a given case should be placed. It is particularly in this lack of definition between the groups that the failure of such classifications is most apparent.

ACUTE NEPHRITIS.

Most of the cases called acute nephritis are cases of acute diffuse glomerulo-nephritis and are represented typically by scarlatinal and tonsillogenous forms. A group of cases has been defined as due to acute *focal* glomerulitis and these are marked by hæmaturia and by a high probability of recovery, and are distinguished clinically from acute diffuse glomerulo-nephritis by the absence of œdema and hypertension and by occurring earlier in the course of an infection such as tonsillitis. Histologically these cases show focal and even partial involvement of the glomeruli, but it is clearly difficult to draw any line between acute focal and acute diffuse forms: histological differences, based on such rare specimens as die, depend on the *amount* of change and the *number* of glomeruli involved, and these are questions only of degree, and in a disease in which a fatal issue is so rare clinical evidence might well be more valuable. But from this aspect we see that both focal and diffuse forms can occur from one common cause such as malaria or relapsing fever, that the absence or presence of œdema can afford no critical division between the forms since the beginnings of tissue œdema are invisible, that hypertension may be absent in acute diffuse glomerulo-nephritis, and that in the late stages of diffuse glomerulo-nephritis the reticular or patchy rearrangement of

UNIVERSITIES YEAR BOOK 1932.

THE Year Book of the Universities of the Empire for 1932, which has just reached us, differs little from its predecessor except that it has 36 more pages and includes a short bibliography of the universities of this country, with particulars of holiday courses and exchange of students. Apart from this there is nothing new; but the alterations and corrections have brought the information scrupulously up to date and make it the useful and authoritative book which it is. There are now 70 British universities, excluding the Hebrew University in Jerusalem, the calendars of which we are told make up the enormous bulk of 50,000 pages, accessible hardly anywhere except at the Bureau of Information for the Universities of the Empire, under whose auspices this book is issued. Sir Frank Heath, in compiling the directory of university staffs and giving in a nutshell the essential information about degrees, diplomas, and scholarships, is laying under his debt not only the universities themselves but all those who are concerned with education. The bureau at 88a, Gower-street, London, is at the disposal of any university member from overseas who visits London. The Year Book is published by Messrs. G. Bell and Sons at 15*s*.

SALVARSAN JAUNDICE.

AMONG the possible causes of salvarsan jaundice are the action of the metal arsenic itself or the benzene radicle combined with it, errors in the manufacture of the drug, faulty preparation or inefficient technique at the time of injection, and the activation of some latent hepatic or alimentary infection. H. Ruge[1] concerns himself with this last aspect of the problem, and bases his conclusions on an experience of some 2500 cases of jaundice observed in the German Navy personnel at Kiel between 1919 and 1929. He observes firstly, that during the ten years before the war the incidence of salvarsan jaundice was 1 in 500, that of simple jaundice among the non-luetic cases about the same. During and after the war there was a notable rise in both types, and in fact of all types of icterus. This general rise in the incidence of jaundice was not confined to the naval depôt at Kiel, but was also observed in the German Army, in the civil population, and also in Sweden, Norway, and the United States. It therefore seems that the exigencies of military conditions and defective nutrition were not the probable causes. Further, the interesting observation has been made that even among the salvarsan injected cases the jaundice may appear in a number of men treated at the same time and in the same clinic. Such "minor epidemics" occurred among naval ratings afloat, where the conditions were favourable to exact observation. It was noted, for instance, that a sporadic case of salvarsan jaundice might be followed some three to five weeks later by a small group of similar cases among men undergoing a course of salvarsan injections. Such an incubation interval strongly suggested infection, and the suggestion was supported by the results of repeated blood counts which during the various phases of the illness closely resembled those encountered in infective conditions generally. This observation naturally led to a routine bacteriological investigation which was performed on numberless occasions. In only 3 per cent, however, was the result positive, the organism being *B. paratyphosus* B. The Widal blood reaction, on the other hand, was positive in a much higher percentage (figure not stated) for this organism. Ruge finally concludes that the actual cause of the jaundice in the two groups of cases (simple and salvarsan) is the same—namely, an organism of the typhoid-coli group. The higher percentage of case-incidences among the salvarsan-injected cases is explained by the added burden of syphilis and of the drug upon a liver which is already infected.

A GENTEEL ADVERTISEMENT.

Dr. C. Willett Cunnington writes: THE LANCE does not usually publish advertisements of professiona abortionists, but possibly you may make an exceptio of the following, partly because of its genteel phrase ology, partly because the advertiser is presumabl by now out of business. The date, as you will see is 125 years ago. It is taken from *La Belle Assemblee* or *Bell's Court and Fashionable Magazine*, o September, 1807.

> "Lost Happiness Regained.—Any lady of respectabilit involved in distress from any expectation of inevitabl dishonour, may obtain consolation and security and real friend in the hour of anxiety and peril, by addressi a line (post-paid) to Mrs. Grimston, No. 18, Broad-stree Golden-square, when a private interview with the advertis will be appointed. Ladies thus situated may depend on t strictest secrecy and motherly attention, combined wi every comfort so necessary on those occasions for the restor tion of that serenity of mind generally attendant cultivated life."

This is the only advertisement of its kind which have found in the ladies' magazines of that perio The delicate wording and the implication of i suggestive title would hold their own against a modern rival.

TWO USEFUL TIMEKEEPERS.

WE have examined two inexpensive watches good appearance which may prove useful to t medical man both in private practice and for gene use. The first is a 30-hour stop-watch with le movement which is guaranteed for two years. T dial is graduated in one-fifth seconds, distinc marked, and has a long second hand by means which accurate pulse readings can be taken. T watch is made in a form suitable for placing on consulting room table or for carrying in the pock as well as for wearing on the wrist; the prices respectively 10*s*. 6*d*. and 15*s*. The second is appointments alarm watch, also with lever movem and a bell inside the back of the case, which ri for some twenty seconds and can be easily set "go off" at any time by moving a pointer to hour required. A reminder can thus be obtained an appointment or of anything which requires to done at an approximately fixed time. This watc guaranteed for three years and is sold at 25*s*.

The watches can be obtained from Messrs. Arn and Co. of 122, St. John-street, Clerkenwell-ro London, E.C.

NIETZSCHE.

A POCKET edition of Nietzsche's famous p poem, "Thus Spake Zarathustra," may find m readers in the medical profession. Speaking genera the state in which much of the world is to-day foreseen in this poem and in other works of "mad" philosopher. To assert 100 years ago t the world required a change of heart because code of morality formulated in Judæa 2000 y ago had proved entirely wrong, was to ask fo condemnation as an impious madman, and that the treatment meted out to Nietzsche, who certainly a difficult subject for classification. world looks now at things differently, and the altera of vision which commenced within the last hun and fifty years, and became more noticeable in middle of the last century, has been a much comm property since the war, and it is striking to find t Nietzsche himself, just before his miserable wrote "I shall be understood after the next Europ war." This new version[1] of his greatest work revision of the well-known translation by Tho Common, the editing having been undertaken Dr. Oscar Levy and Mr. John L. Beevers, the for of whom is the editor of the authorised translatio Nietzsche's works.

BRIGHT'S DISEASE.

E UNITY AND RELATIONSHIPS OF TOXIC NEPHRITIS.

BY HUGH GAINSBOROUGH, M.D. CAMB.,
F.R.C.P. LOND.,
PHYSICIAN TO ST. GEORGE'S HOSPITAL.

RECENTLY much attention has been given to the assification of Bright's disease, with some tendency an increasing subdivision thereof. Further, a rticular dispute has arisen as regards the relation-ip of nephrosis and nephritis. One recent classi-ation presents an entirely new nomenclature). Russell[1]).

Some degree of clarity has emerged, as for example e abolition of such a name as chronic interstitial ephritis, and descriptions of nephritis by the colour nd size of the kidney. New classifications have een based on either the histological picture (Russell) r on this in correlation with the main clinical features Addis[2]). The use of old and new classifications t the same time is confusing, and their multiplicity uggests that they are not yet based on sound natural ivisions, if indeed such exist. In all schemes there re no definite borderlines between the divisions, which hence are grouped arbitrarily in such a way s to accentuate certain main differences, just as he solar spectrum is divided into groups of wave-engths corresponding to our main visual perceptions of colour but without acknowledgment of the gradual transition of wave-length. Some classification of Bright's disease is essential for the convenience of the observer and for descriptive purposes, for the determination of the appropriate therapy, and for the acquisition of knowledge of ætiology, pathogeny, and particularly of prognosis.

So far no scheme is entirely satisfactory when considered from all points of view, and this is perhaps not surprising. Histological examination, however well correlated with the clinical standpoint, must rely on those cases which die; but death is not, as it were, evenly distributed among the so-called "types" of the disease, nor is it easy to build up a *composite* histological picture of the changes which occur in one case from material obtained from different cases at different stages. Even if this difficulty were overcome there are still other troubles in comparing clinical aspects—two cases might present histological features that are very similar, yet in one massive œdema is present, in the other absent. The clinical aspect is further confused by the reliance on so-called tests of renal function which are generally too coarse. A petrol engine may fail to yield its full power for many reasons, there may be increased friction in many parts, or the damage might be in one place, nevertheless the effects of diverse "lesions" on power output might be the same. Addis[3] introduced a method of estimating the amount of reduction of renal tissue, but identical degrees of reduction can be produced by various lesions, and advanced chronic patchy inflammation may reduce the renal capacity as much as an acute diffuse affection. Other methods of estimating renal function—as for example the estimation of blood-urea—are still less adequate, for increase of blood-urea only occurs when the "renal tissue" is reduced by at least 50 per cent.[4] Thus urea retention provides a very arbitrary standard for the comparison of cases of nephritis. Loss of renal function cannot yet be correlated with the histological appearances, the effects on renal excretory capacity of reversible or irreversible changes cannot be estimated, glomeruli normal or almost normal to the eye may yet be leaky filters, as indeed they must be in "genuine" nephrosis.

Addis and Oliver[2] in a remarkable work have simplified the classification of Bright's disease. Their scheme, which corresponds in many ways to the more subdivided one proposed by Russell, is based on clinical and histological studies of fatal cases, the clinical study by the methods developed by Addis being of special interest. Although the main groups are well distinguished, there is still the limitation of a method dependent on post-mortem material, and such groups seem less well defined when the disease is considered in all the aspects of all the cases which are presented to the clinician.

For the starting point of this discussion, the following scheme corresponds to many classifications. Any term belonging to old nomenclature, such as "small white kidney," will only be used in a rough sense sanctioned by long clinical usage.

(1) *Toxic Nephritis.*
  Acute: (*a*) Focal (non-embolic). (*b*) Diffuse.
  Subacute: } Glomerulo-nephritis. Glomerulo-tubular nephritis.
  Chronic: } Large and small white kidney.

(2) *Nephrosis.*
  "Genuine" or "lipoid" nephrosis.

(3) *Arterio-sclerotic.*
  (*a*) Senile (benign nephro-sclerosis). (*b*) Primary contracted kidney (malignant nephro-sclerosis).

The last group will not be discussed in this paper.

The groupings of "toxic" nephritis are rough divisions based on the acuteness or otherwise of the disease process, and it is often difficult to know into which of neighbouring categories a given case should be placed. It is particularly in this lack of definition between the groups that the failure of such classifications is most apparent.

ACUTE NEPHRITIS.

Most of the cases called acute nephritis are cases of acute diffuse glomerulo-nephritis and are represented typically by scarlatinal and tonsillogenous forms. A group of cases has been defined as due to acute *focal* glomerulitis and these are marked by hæmaturia and by a high probability of recovery, and are distinguished clinically from acute diffuse glomerulo-nephritis by the absence of œdema and hypertension and by occurring earlier in the course of an infection such as tonsillitis. Histologically these cases show focal and even partial involvement of the glomeruli, but it is clearly difficult to draw any line between acute focal and acute diffuse forms: histological differences, based on such rare specimens as die, depend on the *amount* of change and the *number* of glomeruli involved, and these are questions only of degree, and in a disease in which a fatal issue is so rare clinical evidence might well be more valuable. But from this aspect we see that both focal and diffuse forms can occur from one common cause such as malaria or relapsing fever, that the absence or presence of œdema can afford *no critical* division between the forms since the *beginnings* of tissue œdema are invisible, that hypertension may be absent in acute diffuse glomerulo-nephritis, and that in the late stages of diffuse glomerulo-nephritis the reticular or patchy rearrangement of

5674

the kidney substance would indeed suggest that the initial injury had not been equally diffused.

Thus acute focal and diffuse forms may well have a common causation, and the differences between the two forms are only a matter of degree.

NEPHROSIS.

The distinction between chronic glomerulo-nephritis and "genuine" nephrosis is still less well defined, while the similarity between these groups is very striking. Elsewhere [5] I have expressed the opinion that there is no justification for separating off a group of cases as "genuine" or "lipoid" nephrosis, but as this conception still holds sway in many quarters, certain aspects of the argument are worth repeating and extending. I would here quote from Leiter's [6] review of the subject:

> "The nephrotic syndrome seems to be well established clinically and pathologically as something not directly related to glomerulo-nephritis or inflammatory renal disease, though commonly associated with it. In its *primary*, uncomplicated form, this syndrome is known as nephrosis and is a rare *disease*. The rarity of this disease, however, is no justification for the denial of its existence." (I have rearranged the italics.)

In brief, the main features of nephrosis comprise a chronic degenerative lesion of the renal epithelium in which glomerular change is slight or invisible, a prolonged course marked by œdema and the absence of hæmaturia, hypertension, or nitrogen retention, and the occurrence of heavy albuminuria. The albumin to globulin ratio in the urine is about 20 to 1, and if this is compared to the albumin to globulin ratio in the plasma (viz., 2 to 1) it is easy to realise that the proteinuria leads to a relative depletion of the plasma albumin. The plasma, apart from low albumin content, often contains an actual increase in globulin and fibrinogen content, and this has been explained by the results of plasmapheresis experiments in which it has been shown that fibrinogen and globulin are more easily regenerated in the plasma than albumin. Thus ensues a lowering of colloidal osmotic pressure from the loss of albumin and this is not balanced by the increase of globulin, for this protein with its greater molecular weight has relatively a smaller effect. The normal colloid osmotic pressure of the plasma is about three times the capillary blood pressure, but in these cases it often falls to below this latter value. This change is probably the main cause of the anasarca, which though a principal feature of the disease, is relapsing in character and may be absent for long periods. Clearly, considerable plasma albumin depletion can occur before the colloid osmotic pressure is sufficiently lowered for this cause of œdema to be operative. Changes in sterol metabolism occur including gross hypercholesterolæmia, increase of cholesterol ester content of the kidney, and increased cholesterol excretion in the urine. There may also be a lowered basal metabolic rate, even in the absence of œdema, and often a moderate degree of leucocytosis.

Now all these features are frequently seen in cases of subacute glomerulo-nephritis or large white kidney, but in these cases the period in which the clinical and metabolic state is indistinguishable from the above described syndrome may be preceded or associated with slight hæmaturia. Later, however—it may be months or years—as the renal changes progress towards sclerosis, the picture changes, the tendency to œdema vanishes, the hypercholesterolæmia returns to normal, and hypertension and nitrogen retention appear, though not necessarily simultaneously. With hypertension may follow rapidly advancing changes in the fundus oculi and in the size of the heart, and when persistent nitrogen retention is obvious the case is approaching death in uræmia. Sometimes a gross nitrogen retention passes off for a time, but it almost always recurs, and the ultimate end seems unavoidable. Both in such cases of subacute glomerulo-nephritis with the so-called nephrotic tendency, and in so-called genuine nephrosis a large proportion of cases manifest as a usually fatal complication, pneumococcal o streptococcal infections, more commonly a peritoniti but sometimes an empyema or an erysipelas. Thi is well shown in the cases reported by Fahr.[7]

The fate of cases described as genuine nephrosis still somewhat doubtful. Some cases undoubtedl recover, but the majority die with septic infectior as just described. "True uræmia never occurs, says Leiter [6]; but then of course the case would n be one of "genuine" nephrosis, by definition!

The general clinical similarity of "genuine nephrosis and some forms of subacute glomerul nephritis is indeed very close, the differences a sometimes very little, and it is possible to find series of cases of subacute glomerulo-nephri presenting to an increasing degree the nephro syndrome. *Such cases have been termed* nephr with nephrotic tendency (nephrotische Einschl *and are considered by some authors* as a mixture two diseases or disease processes (Murphy Warfield [8]). Recent reports of cases of "genui nephrosis are so scrutinised by critics that the l departure from the definition of *the disease* is s cient reason to relegate a case from the group nephrosis to that of nephritis, and a blind ey turned to the overwhelming degree of similarity— Murphy and Warfield's [8] criticism of some of Dyk cases, and Leiter [6] on Bell.[10] It is, in fact, diffi to find cases which satisfy all criteria, and such c as do so are almost always cases which have ei recovered, or terminated, as it were accident *from an infection.* *What* would happen if infec did not occur is yet to be discovered. It is impor here to note that the cases of glomerulo-nepl which present at some time the nephrotic synd in purest form are those cases which have the lo course and greatest chronicity.

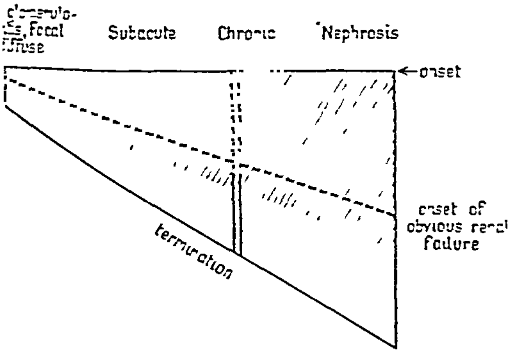
The argument for including nephrosis in the g of glomerulo-nephritis has been detailed from clinical and histological view-points by Christi and by Bell.[10] *The latter demonstrated by* a bea technique the histological relationship of nepl and glomerulo-nephritis. The histological cha which characterise "genuine" nephrosis, an al pure epithelial degeneration, equally occupy picture in the early stages of subacute glome nephritis, even if more definite inflammatory cha in varying degree, are present as well. Bei and co-workers [12] find no adequate reason for tinguishing between the three cases of nepl reported, although one died in uræmia with a l logical picture more resembling nephritis. say that the separation of this case from the ot suggested on anatomical grounds, "becomes ill and insufficient when all aspects of the case fully reviewed."

Lohlein [13] and Bell [10] believe that nephros only an example of chronic glomerulo-neph whereas Elwyn [14] *thinks that nephrosis fo* acute diffuse glomerulo-nephritis. The former that nephrosis is part and parcel of glome nephritis, seems to me the only possible explana and it is quite unnecessary to assume that i yn suggests, a sequel of an acute diffuse tis which has healed atypically leaving purely rative processes.

CAL NATURE OF ALL FORMS OF TOXIC NEPHRITIS.

iscussing the relationships of different forms merulo-nephritis confusion arises from the use terms acute, subacute, and chronic; sometimes terms are used in the sense that a chronic bacute process may follow an acute one, imes in the clinical sense of the duration of sease, sometimes as an index of the severity inflammatory process in the kidney. It seems simplest to use these terms as signifying rate gress of the disease, by which means one becomes ndent of such an extremely variable figure as tual duration. Each case appears to have an ge rate of progress, whether considered from ical or histological point of view, and it is hat determines the "type" of the case, but of the actual rate varies at times by exacerba- r quiescence.

elieve that "genuine" nephrosis and all forms omerulo-nephritis are essentially of the same e and are caused in a similar manner (even h the activity and nature of the actual causal may be different), and that the difference en the various groups is mainly one of degree. mined by the average rate of progress of the e. Each and every case tends, as a case of phritis," towards renal failure evidenced by gen retention and hypertension and on each is superposed a variable amount of the phrotic" syndrome, with its metabolic changes sequel of proteinuria. In acute forms of nephritis nephrotic syndrome is hardly manifested at in less acute forms this syndrome becomes easingly apparent but overlaps in varying degree more obvious signs of renal failure. In chronic s the nephrotic syndrome occupies to a large ree, or entirely, the whole clinical picture, and nary signs of nephritic failure may never appear use the cases either die of infection, or recover. re such can occur. In other words "genuine" hrosis can only occur when the underlying hritis is so mild that renal sclerosis and its ptoms do not complicate the development of nephrotic process. This conception can be sented diagrammatically as shown.



shaded area represents the addition of the nephrotic syndrome.

The ordinates represent in a rough way the duration the disease, and different cases can be represented narrow vertical columns. The classical groups are sented by the headings, no lines of demarca- n being drawn between them. The scheme demonstrates the transition from one end of the scale, representing acute hæmorrhagic nephritis of relatively short duration, to the other end, representing the more chronic forms in which, for reasons already given, the nephrotic syndrome comprises almost the whole or the whole of the picture.

The "metabolic" addition of nephrosis is represented in values which gradually increase as the duration of the renal disease allows its more complete development. Each case presents a progressive loss of renal function, though not necessarily an even progression, till below the dotted line the renal failure becomes obvious by the coarse manifestations of nitrogen retention and hypertension. In acute cases the clinical picture is dominated from an early stage by this "nephritic" syndrome, in subacute cases this syndrome appears later but generally overlaps more or less whatever degree of the "nephrotic" syndrome that is present, in the most chronic cases coarse renal failure *follows* the nephrotic stage if the development of the case has not been interrupted by death or recovery.

Below the dotted line the scheme suggests that gross loss of renal function in the most acute and in the more chronic forms is identical in nature and uniform in effect, whatever may be the activity or nature of the toxin (assumed or known), and whatever may be the histological changes present.

Cases which are widely separated in the scheme may well have an identical causation. Excellent examples of this were seen in trench nephritis. Here, some cases were marked by fever, hæmaturia, and slight œdema, others were less sudden in onset, had little hæmaturia, but anasarca and a more prolonged course provided the main features. "The general manifestations of the disease—epidemic occurrence, generally febrile onset, bronchitic phenomena, frequent splenic enlargement—all point to a primarily infectious origin of the disease" (Fishberg[15]). It must be very probable that, whatever may have been the predisposing causes of such an epidemic, the infecting agent was unique yet it could produce glomerulo-nephritis of such different types.

These considerations compel us to look for some unity in the cases, however much the outward manifestations differ; and by a mental exclusion of the nephrotic addition, such unity is clearly shown in this scheme, whereby the differences are emphasised as a matter of degree, and an expression of the average rate of progress—this being probably the resultant of the intensity or activity of the toxin and the humoral and tissue resistance.

Probably the best examples of "genuine" nephrosis have been presented by cases of luetic origin. These do not need separate classification for, in accordance with our knowledge of the extreme chronicity of processes due to such infection, renal change would be expected to be equally slow, so slow in fact that measurable loss of renal function is rarely demonstrated. Yet even here a case I have observed presented a retinitis albuminurica at about the time of the abatement of an anasarca which had lasted thirteen months. Complete recovery occurred in this case even though a fresh luetic infection was acquired soon after his discharge from hospital.

In terminal stages of the disease, hypertension results in arterial and arteriolar changes, retinitis, and enlargement of the heart. The two former of these changes can be produced sometimes so rapidly that it is difficult, in the absence of further proof, to believe that they are expressions of increased mechanical strain acting solely, but that, in some other way, the renal lesion must be responsible therefor. However it may be produced, advanced vascular changes may alter the histological picture and produce, as it were, an added ischæmic nephritis.

In the diagram one column is partly represented by dotted lines to correspond with the initial stages of the disease. Such cases are those of small white kidney, or secondary contracted kidney, or nephritis repens (Russell [1]). As a rule these cases are observed only in terminal stages, the initial stages are so devoid of symptoms that the patient often fails *to note the onset of the disease. If œdema is absent*, hæmaturia and albuminuria can easily be overlooked. In such cases the loss of plasma albumin is probably insufficient to lower the colloid osmotic pressure below the capillary hydrostatic pressure; it is to be remembered that normally there is a large margin in the excess of the former, and as a result the sum total of the factors which produce œdema do not reach a sufficient value. In other respects these cases in no way differ from neighbouring cases in which œdema has been present, except perhaps in the consequent lack of treatment. These cases proceed to advanced changes in the renal structure in which the final fibrotic processes may be patchy (reticular) or diffuse. The terminal stages are often complicated by severe ischæmic nephritis.

It is to be noted that every case of toxic nephritis is essentially azotæmic, and that the superposition of "nephrosis" in sufficient degree provides the so-called hydropigenous forms. Clearly then it is useless to divide nephritis into azotæmic and hydropigenous forms.

PROGNOSIS.

The prognosis of toxic Bright's disease confronts us with difficult problems. At the one end of the scale the acute and grossly hæmorrhagic forms present an exceedingly good outlook, recovery occurring sometimes very quickly and sometimes a matter of months. Occasionally the treatment of sepsis—e.g., by removal of septic tonsils—seems to be necessary, and the temporary exacerbation of symptoms which so often follows suggests a correct location of the cause. However, as one proceeds along the scale to less acute and chronic forms, the ultimate prognosis seems to be much more grave. Cases which manifest definitely the nephrotic syndrome, apart from the risk of death from infection, show progressive renal destruction, and a termination in uræmia. The prognosis of the "pure" nephrotic cases has already been suggested.

These prognoses are very puzzling, for apparently the less active processes of subacute forms present a worse outlook than that of the most acute cases. This does not appear to be the effect of the "nephrosis," for though Barker and Kirk [16] thought that renal changes could follow experimental depletion of plasma proteins, this has not been confirmed by Leiter.[17] Possibly the prognosis depends to a considerable extent on the persistence or disappearance of the causal "toxin." Acute nephritis following scarlet fever or acute tonsillitis is generally of excellent prognosis, as if the disappearance of the causal infection determines recovery. Nevertheless, though in some cases a toxin of streptococcal origin seems to be well evidenced as a cause in tonsillitis and scarlet fever, the existence of a toxin in other cases is merely assumed by analogy. Unfortunately we are not in a position to gauge the persistence or otherwise of the toxin, and the prognosis in an individual case can only be roughly guessed. Nevertheless the possibility of recovery is present in cases in which the "group" prognosis is usually bad. I would quote three such examples.

CASE 1.—Male aged 53. Œdema of feet appeared in December, 1926. Urine albumin +. No hæmaturia. B.P. 120/80. Œdema soon vanished but recurred at intervals for the next twelve months. Wassermann reaction negative. *By* June, 1927, there was a syst. B.P. 150, blood-urea 0·03 per cent.; a small hæmorrhage appeared in left retina in August, 1927, B.P. 180/110, and a month later there was definite "arterio-sclerotic" retinitis which by January, 1928, had become typical "renal" retinitis, with B.P. 210 syst., and blood-urea 0·037 g. per 100 c.cm In May, 1928, the B.P. was a little lower, there was some improvement in the fundi, blood-urea 0·06 g. per 100 c.cm. In November, 1928, the retinal changes had almost completely disappeared though albuminuria was still quite persistent. Since that date the retinæ only show slight vascular change, the B.P. has steadily fallen to a constant level of about 145/90, the albuminuria has progressively diminished, there is none at present, and during the past six months faint traces only have been occasionally detectable.

CASE 2.—Male aged 37. Œdema first noticed May, 1929, when the urine was found to contain a little blood and much albumin. The œdema steadily increased in amount (though not to anasarca) and persisted for two months. The urine albumin varied from 0·2 to 0·4 per cent. By the end of August, 1929, the albuminuria had vanished but soon recurred, there then ensued a steady increase of B.P., and from December, 1929, to February, 1930, was at a level of about 190/110. No nitrogen retention or change in the fundi. Since then there has been a steady fall of B.P. to 130/100 and the proteinuria has vanished completely. The urine now contains no cells or casts.

CASE 3.—Female aged 16. Swelling of face, ankles, and legs appeared Nov. 2nd, 1927. Albuminuria 0·9 per cent. Slight hæmaturia for a few days. Œdema persisted for three months, during which time plasma cholesterol reached a total of 0·37 per cent., syst B.P. varied between 90 and 122, no nitrogen retention occurred. Some leucocytosis during the early stages, total whites 14,840 with 72 per cent. polymorphs. Albumin-globulin ratio in urine 21/1. Tonsillectomy March 21st, 1928. Albuminuria thereafter diminished and there was only a trace detectable two weeks later, when she left hospital. Seen six months and eighteen months later; no evidence of nephritis could be detected.

The first case is somewhat astonishing, for the rapidly advancing vascular changes were so typical of a nephritis which had progressed beyond all hope of recovery, and yet in the past three years there has been progressive improvement (even if one hesitates to speak of cure), with regression of the vascular changes evidenced by the blood pressure and the retinal picture, and with disappearance of the albuminuria.

NOMENCLATURE.

It seems to me to be sufficient at the moment to describe one comprehensive group of toxic nephritis including a range of cases in which the whole picture varies from the mildest to the most severe affection. The terms mild and severe refer both to the nature of the histological changes and to the average rate of progress. Those cases advancing most rapidly and with the acutest type of inflammatory change are "severe," and those which progress most slowly and with the least acute type of inflammation are "mild." It is understood however that, in a clinical sense, the "mild" cases may present great dangers to life from the addition of the nephrotic syndrome.

Finally I would draw attention to two problems. The first is in respect of the disappearance of the nephrotic syndrome in the later stages of nephritis, for when vascular changes and gross nitrogen retention appear the tendency to œdema and the hypercholesterolæmia vanish. The disappearance of the œdema may be due possibly to diminished loss of tein, or to changes in capillary states, but even t is found later that the colloid osmotic pressure s rise above the level where œdema is likely to ear, it is still very difficult in our present state knowledge to suggest any working hypothesis explain the fall of the hypercholesterolæmia. e second, which has already been mentioned. he question as to whether there is a persistently ing toxin or not in progressive nephritis.

CONCLUSIONS.

Toxic nephritis is a disease in which progressive nges in the kidneys, of the most variable severity. associated with a clinical picture which presents mity, despite the differences which are due mainly the length of duration of the process.

From the most acute forms to the mildest forms, ery degree of severity can be found, and it is possible to find natural subdivisions.

"Nephrosis" comprises a clinical and metabolic drome which is superimposed upon all cases toxic nephritis, to a degree depending mainly the mildness of the nephritis and consequently the length of time available for this syndrome develop. The most nephrotic cases are those which the nephritis presents the mildest histo- gical changes and the slowest rate of progression.

All cases of toxic nephritis present a progressive s of renal function and tend to terminate in æmia. In the most nephrotic cases this change so slow that such cases die usually from inter- rrent infection, or recover, before loss of renal ction, as usually measured, is recognisable.

The nature of this progressive loss of renal function identical in all cases of toxic nephritis, whatever e cause and whatever the severity.

I wish to express my indebtedness to my medical olleagues at St. George's Hospital for their kindness n allowing me freely to study and observe cases of ephritis under their care.

THE FLIGHT FROM THE "COTTAGE HOSPITAL."—To the several instances in which cottage hospitals have recently changed or proposed to change their name to general hospitals must now be added Bexley, in Kent. At the annual meeting at which the change was proposed it was stated that the institution was established "in the days of flannel poultices," and that in consequence of the volume of work the old name is now detrimental. One of the arguments in favour of the change of title to "Bexley and District Hospital" was that larger subscriptions might then be expected from societies "which very often do not look very highly upon cottage hospitals." The matter was remitted for further consideration.

SPONTANEOUS SUBARACHNOID HÆMORRHAGE.*

BY ARTHUR J. HALL, M.A., M.D., D.Sc.,
F.R.C.P. LOND.,

EMERITUS PROFESSOR OF MEDICINE, UNIVERSITY OF SHEFFIELD; VISITING PHYSICIAN, SOUTH YORKSHIRE MENTAL HOSPITAL AND RAMPTON STATE INSTITUTION.

SUBARACHNOID hæmorrhage has long been known as an occasional cause of death. From time to time fatal cases came to autopsy in which there had been no injury, and no disease sufficient to explain the bleeding was found. Until lumbar puncture came into general use, however, that is to say the last 15 or 20 years, it was not general knowledge that subarachnoid bleeding not infrequently occurs without causing death. It is true that such an event had been observed. Thus, Gowers,[1] writing in 1888, three years before Quincke introduced lumbar puncture, says: "In slight cases (*of meningeal hæmorrhage*) recovery is possible, as subsequent post-mortem has proved." To-day, thanks to Quincke's work, in all forms of meningeal disorder the condition of the cerebro-spinal fluid can be ascertained at the time of the symptoms and the two thus readily correlated. This has done for the meninges what laparotomy has done for the abdomen; it has made a dark place light, facts have replaced fantasies.

One of the results is that we have now a clear and easily recognisable clinical picture of what is called spontaneous subarachnoid hæmorrhage. This may occur at any age. It has been seen in quite young children, and in elderly persons; it is however most common in early adult life before the blood-vessels have begun to undergo the changes of later years. The person affected is usually in excellent health at the time, and in many cases there is no history of previous illnesses or of any symptoms pointing to head trouble at any time. In a certain number of recorded cases, however, there is a history of head symptoms of various kinds from time to time; this will be referred to later.

The onset, as might be expected, is usually sudden. The patient may fall down unconscious and may remain so until death. As a rule, such unconsciousness usually passes off sooner or later. If there is no actual loss of consciousness the onset takes the form of severe pain in the head, usually in the occipital region. Some patients say that it felt as though they had been struck a violent blow, others, as though something had snapped inside. Sometimes it is less severe at first and soon increases so as to make the patient cry out.

In addition to headache there is usually recurrent vomiting of cerebral type. There is often more or less confusion. There may also be restlessness and general pain. At times the patient is strange in manner and resents interference. A slightly raised temperature which in some cases persists for several days is common. Where there has been a primary loss of consciousness this may pass off in a few hours, leaving the patient confused and complaining of headache and sometimes of pain in the limbs. The pupils may be dilated, contracted, or unequal. There is, as a rule, no paralysis and no sensory change, but hemiparesis or ocular palsy may occur. The condition of the reflexes varies. The knee-jerks may be normal, increased, unequal, or as in one of my cases *absent for several days*. The *plantars may be normal*, or they may show toe extension on both sides or flexion on one and extension on the other. In one of my cases there was in each foot perfect flexion when the inside of the sole was stimulated, and equally perfect extension on stimulating the outer side. Kernig's sign may be present on one or both sides or it may be absent. The urine often contains a trace of albumin. Sometimes there is a large amount. This so-called "massive albuminuria" is not common. When present it is often misleading as it suggests uræmia, with which these cases have certain points of similarity. It usually disappears in a few days, and as was shown in a fatal case which I saw in 1929, the kidneys may be found to be normal at autopsy.

---

* Read before the Sheffield Medico-Chirurgical Society, March 31st, 1932.

The fundi may show characteristic changes of great diagnostic value. Intra-ocular hæmorrhages, into the retina or vitreous, or more rarely, choked discs, may be present. Riddoch and Goulden[2] consider *that these are due to distension of the subarachnoid* space round the optic nerve, with separation of the dural and pial sheaths, causing raised pressure and traction on the vein, and sudden interference with the venous return. Epileptic attacks may accompany the bleeding. Their occasional occurrence during the illness, without evidence of further bleeding, will be referred to later.

In a case presenting the more constant of the above features, a diagnosis of subarachnoid hæmorrhage may usually be made with confidence, and lumbar puncture is indicated at once. As a rule the fluid is found to be at a somewhat increased pressure, and to contain blood in variable quantities. That the blood is not merely due to injury by the needle must be made certain in the usual way by noting that the blood is equally present in three separate lots of fluid, by the absence of clotting, and by the supernatant fluid being blood stained.

Although this condition is often spoken of as "spontaneous" subarachnoid hæmorrhage, yet it is not always quite without an immediate cause, in the form of some increase of excitement or of muscular activity. This may be so slight as to be hardly recognisable, or it may be quite definite, although something less than actual trauma. That there should be an immediate cause is not surprising. If, as is so often the case, it is due to the rupture of an aneurysm, the actual burst is only the culmination of a gradual process of giving way, with coincident attempts at repair. There may be no symptoms until the last defence has broken down. Even then it may be only a minute oozing, perhaps best described as "leaking." In other cases it may be much more than this.

Progress.

The first attack may be very severe and prove fatal without even temporary recovery. On the other hand the onset may be severe with complete loss of consciousness, and after a few hours, or even less, the patient begins to come round. What happens then depends on circumstances. There may be no further bleeding with gradual recovery. On the other hand, further bleeding is liable to occur, which in turn may be recovered from, or may be of fatal severity. Even if kept at absolute rest in bed recurrences may occur, depending on the conditions inside the skull.

Symonds[3] has made a useful division of these cases into four groups according to their severity.

Group 1.—Sudden large hæmorrhages causing apoplectiform effects which go on till death sooner or later.

Group 2.—Initial apoplectiform onset, gradually changing to mental confusion and recovery or possibly death from a further attack.

Group 3.—Milder onset without coma, either getting gradually more severe or improving.

His fourth group is more or less hypothetical and need not concern us here.

The following case is an example of Group 1. It occurred before the days when lumbar puncture was a routine procedure.

CASE 1.—A man of about 40 years, whilst playing in a cricket match, hit a "four" and immediately fell down unconscious. He was admitted to the Sheffield Royal Hospital on August 20th, 1904. On admission he was unconscious and remained so until death. There was stertorous breathing. No squint. Pupils equal, medium size. Conjunctivæ sensitive. No evident hemiplegia. Moved both arms slightly at times. Knee-jerks present both sides —also toe extension. No superficial reflexes obtained. There was a trace of albumin in the urine. He died on August 25th, the sixth day.

At *autopsy* an aneurysm the size of a small pea was found on the left anterior cerebral artery. It had burst in front and the blood had ploughed up a rounded cavity in the ventral surface of the frontal lobes about 2·5 cm. in diameter. The right was more excavated than the left. It had destroyed the lower part of the genu of the corpus callosum, pushed back the anterior white commissure and just reached on each side to the floor of the lateral ventricle; on the left *side it had actually penetrated the ventricle*, but there was only very little blood in the ventricles. The chief spread of blood had been along the subarachnoid space, tracking widely over the whole surface—more on the left side than on the right. There was also atrophy of the right kidney, due to an impacted ureteral calculus, but no evidence of chronic nephritis or arterio-sclerosis.

In this case the immediate determining cause was undoubtedly the very considerable muscular effort of hitting a "four," but up to the time of its rupture the aneurysm had shown no signs or symptoms of its existence. Its site is the common one for this type of aneurysm—namely, at or about the junction of the anterior and middle cerebral arteries.

The next two cases come under Group 3.

CASE 2.—On April 21st, 1931, a single woman, aged 35, apparently in excellent health and full activity, on her way home at night had run to catch a tram, and then mounted to the upper deck. Whilst sitting there she suddenly felt an intense pain in the back of the head, neck, and trunk. She had a very restless night owing to pain and vomiting. Temperature 100°. Next morning I saw her with Dr. Paige. The pupils were unequal; the neck was stiff and movement caused pain; the reflexes were normal; there was definite Kernig's sign on both sides. There was a good deal of nervous alarm, but no real mental confusion. Lumbar puncture showed an increased pressure and the fluid considerably blood stained.

She gradually improved in every way, but on April 27th, that is the seventh day, she had more pain in the head and vomiting recurred during the next 24 hours. Kernig's sign, which had practically disappeared, was again marked on both sides and she complained of pain going all down the spine in a quite unusual way. From that time onwards she made a steady recovery and is to-day in her usual health.

This was a typical mild case. The most interesting feature was the return of pain and vomiting on the seventh day. It naturally raised the suspicion of further bleeding, but as it subsided quickly it seemed more likely that the increase of symptoms was due to the changes taking place in the blood already in the meninges, and the possible irritant effects of products of metabolism on the highly sensitive membranes. The question of a further lumbar puncture arose, but as thè symptoms subsided in a few hours it was not considered necessary.

The cause of exacerbations during the progress of a case is of considerable interest. It is natural to suspect further bleeding, and this sometimes occur even in non-fatal cases, but it is not ys so.

somewhat similar exacerbation was seen in the case also.

se 3.—This was a married woman, aged 25. She not had any previous illnesses. About the end of mber, 1926, whilst stooping down to put some coal on fire, she felt something "snap" in the back of the . This was immediately followed by intense pain from back to the front of the head. She turned faint and to be carried to bed. Severe vomiting occurred for next hour or two. The pain was very severe in the tal region for the next few days, and she had to keep head upright. If she moved it to either side she said felt as if it were full of liquid." During the next two ks she improved, but on Jan. 16th, just before dinner, had a severe epileptic fit, followed by intense headache k and front and severe vomiting.

was asked to see her on Jan. 27th—that is about 21 or ays after the original attack (they were uncertain as to date)—and 11 days after the exacerbation with the eptic fit.

n Feb. 2nd she consulted Dr. Collier—lumbar puncture done by him on that day—that is, 17 days after the erbation, and between 27 and 34 days after the original ck. He tells me that the cerebro-spinal fluid was then a faint primrose yellow colour that it could only be gnised in a strong light. Had there been a second orrhage on Jan. 16th it is probable that the fluid would e been more coloured than that. Froin (quoted by onds[3]) records a case in which the cerebro-spinal d from a non-fatal case (of Group 2 type) showed formly yellow on the seventeenth day, and very slightly ow on the thirty-third day. It seems, therefore, more bable that the exacerbation of symptoms with an epileptic ack which only occurred 17 days before lumbar puncture not been due to further bleeding.

r. Collier, in a private communication, also tells me that les occurring at onset epileptic attacks during the time recovery possibly due to absorption of the blood are very rare, and that, in his opinion, actual recurrences leeding in these cases are probably not so common as they thought to be. It has not been possible to follow up case.

That recurrent bleeding may occur within a few ys, even more severe than the initial attack and end in recovery, is suggested by the next case:—

CASE 4.—On Jan. 10th, 1928, I received an urgent call see a man, aged 36, who was unconscious and thought be dying. The history was that on Jan. 6th, whilst full health and vigour, he had suddenly been seized with intense pain at the back of the head. He got home with ulty, vomited several times and went to bed. Next the headache continued, the temperature was 100°, eyeballs felt tender, and his neck was stiff. On Jan. 9th, ugh still feeling ill, he got up and went downstairs. In evening he took some purgative pills. Next day he ayed in bed in the morning, got up to go to the closet, and ut midday was found comatose in bed. I saw him with . Greaves at 3.30 P.M., the breathing was noisy, irregular, d of Cheyne-Stokes type, the pupils were small; there s a divergent squint. The pulse was increased in quency and of low pressure; there was no Kernig's n; the legs were flaccid, slight toe extension on the right e; no response on the left; no knee-jerks were obtained. e diagnosis of subarachnoid hæmorrhage was confirmed lumbar puncture. The fluid flowed freely and was blood ined throughout.

During the next few hours the coma passed off. It was lowed by complete confusion, which with pyrexia tinued for about a fortnight. As the confusion inished he developed a condition resembling Korsakow's drome which persisted for several weeks and was a rce of great anxiety to his friends. It passed off pletely in time, and to-day, four years later, he is in tive work.

In this case there was a primary bleeding on an. 6th, and there can be little doubt that further eeding occurred on the 10th, that is, on the fifth ay. The effects on the second occasion seem too vere and too prolonged to be explained in any other way.

A second point of interest in this case was the olonged disorder of his mind. It simulated that en in alcoholic neuritis. For many weeks he had plete loss of memory for recent events, together with surprising powers of confabulation. Although apparently quite well in his general health, yet if asked what he had done the day before, he had not only entirely forgotten, but with perfect assurance, would describe entirely imaginary events in detail.

The occurrence of Korsakow's syndrome in this condition was first recorded by Goldflamm.[4] His experience is that it always clears up in time, and this case fully confirmed his view. Another point of interest in this case was the pain in the back of the eyeballs. Although no intra-ocular hæmorrhage or choked disc was found, it is probable that this pain was due to the distension of the subarachnoid sac around the optic nerve.

The next case, though by itself not in any way unusual, is of interest in connexion with the pathology of this condition.

CASE 5.—On Jan. 6th last I was asked by Dr. Norton Milner to see a single woman, aged 46. She had never had a day's illness since childhood. During the night of Dec. 27th she got out of bed and was heard to fall. They found her unconscious on the floor. By the time Dr. Milner saw her she had recovered consciousness but was confused, although able to answer questions. She had vomited several times. Temperature 100°. She complained of violent pain in the right side of the head. There were no abnormal physical signs. She was kept in bed and, except for the headache over the right temple, seemed to be improving. On Jan. 6th, about 3 A.M., that is 11 days later, she was again heard to fall, and again was found on the floor unconscious. This time Dr. Milner noticed a slight left facial paralysis.

When I saw her later in the morning she was quite rational and talked sensibly. She complained of pain over the right temple, and also told us that after the first attack she had had severe pain at the back of the neck and down her back. There was a slight left facial paresis, the grasp of the left hand was weaker than that of the right. The knee- and ankle-jerks on the left side were more marked than on the right, and although there was no definite toe extension on either side, yet while the response on the right was definitely flexor, that on the left was indefinite. No changes were seen in the fundi. There was a trace of albumin and the temperature was slightly raised. From the history alone a diagnosis of subarachnoid hæmorrhage was probable, and this was confirmed by finding the cerebro-spinal fluid uniformly blood stained.

Dr. Milner tells me that she made a steady recovery and is now in her ordinary health.

At the time that I saw this patient on Jan. 6th last, I was told by her relatives that her mother had a somewhat similar attack in 1913, and that I had seen her at that time. The following record of the mother's illness is from my notes taken at the time.

CASE 6.—On May 2nd, 1913, I saw her with the late Dr. Shea at Chesterfield. She was then 62. Five days before, on May 17th, she had suddenly fallen down unconscious and pulseless. There was severe vomiting; no local paralysis: pupils small and equal. She came round in about half an hour, complaining of intense occipital pain. Since then she has been more or less drowsy and stuporose. The urine is scanty and contains a little albumin. In the right fundus oculi there is a large hæmorrhage lying across and below the lower half of the disc, and another smaller one near the upper edge. The temperature is slightly raised. No paralysis or sensory loss.

At that date, nearly 20 years ago, the clinical picture of this syndrome was not familiar, and lumbar puncture was not a routine procedure. The case puzzled us a good deal, the diagnosis seeming to lie between uræmia and a cerebral thrombosis in some silent area. At any rate I made a special mark on my notes to follow up her after-history. Three years later, in 1916, I heard, to my surprise, that she had recovered completely without any paralysis and that the ocular hæmorrhages had cleared up. Again in 1924, that is 11 years after the attack, I was told that she was quite well. As a matter of fact she lived until 1930; that is for 17 years.

Here, then, is a clear instance of spontaneous subarachnoid hæmorrhage in two members of one family, mother and daughter. Both occurred rather later in life than is common in this type of case. The diagnosis in the daughter's case was made certain by finding blood in the cerebro-spinal fluid. In the mother this was not done, but there is not the least doubt as to the nature of her attack. Not only were the symptoms characteristic but the finding of intra-ocular hæmorrhages, which eventually cleared up, is almost as strong a confirmation as would have been the presence of blood in the cerebro-spinal fluid.

The question of a family tendency is of much interest in connexion with its ætiology. Gowers recorded its occurrence in two brothers. Dr. Greenfield in a private communication tells me of another instance, not as yet published, "in a woman of 54, whose daughter had died at the age of about 20 from what was thought clinically to be influenza, but was found post-mortem to be a ruptured cerebral blood-vessel." Another suggestive family series has been recorded by Goulden and Riddoch.[5] If, as is generally agreed, many of these cases of subarachnoid hæmorrhage are due to the leaking of a so-called "congenital" aneurysm, it would seem likely that from time to time more than one such would occur in the same family. Perhaps the term "developmental" or "familial" would apply more fitly to them than "congenital."

Some interesting observations have recently been made by Wiley Forbus [6] on the origin of these miliary aneurysms of the superficial cerebral arteries. In a case with multiple aneurysms in the circle of Willis, he found that all of these were situated at similar places—namely, at the point of the acute angle where there is a bifurcation. He also found that the walls of the aneurysms contained no tunica media. He then examined other arteries (from the same case) in which there was no aneurysmal dilatation, and found that in a number of identical positions there were similar gaps in the continuity of the tunica media. Similar gaps were also present at similar points in specimens from other cases of cerebral aneurysm, and also in the vessels from other persons in which there was no aneurysm at all. They were also found from time to time in the coronary and mesenteric arteries.

These defects of the muscular coat were only found at the points of bifurcation. They showed no signs of inflammatory changes, arterio-sclerosis, or external trauma. He therefore concludes that the actual aneurysmal sac is an acquired lesion arising from a congenital defect of the muscularis: that it is probably contributed to by a gradual degeneration of the elastic membrane, due to continued over-stretching of this membrane. In some the defect does not lead to aneurysm, in others aneurysm may be present, but it has not ruptured, whilst in still others it is the rupture of the aneurysm due to the defective muscularis that has caused the immediate symptoms. These observations of Forbus have been confirmed by Greenfield [7] in five cases of intracranial aneurysm.

It may be objected that in my two cases it is difficult to exclude arterio-sclerotic changes in the mother at 62 years of age. It seems even more difficult to imagine an arterio-sclerosis of such severity as to lead to a burst, yet causing no further cerebral symptoms for the next 17 years.

The next case, though in many ways similar, differs from the preceding in several respects.

CASE 7.—A single man, aged 28, was sent to me by Dr. Bellamy of Scunthorpe on June 5th, 1930. He had always been an active athletic man. On May 12th—that is about four weeks before I saw him—whilst boxing, he was knocked down by a blow on the head. This stunned him and was immediately followed by a violent headache and vomiting, so that he stayed in bed for the next two days. On the third day he got up and drove his car from Lincolnshire to London. The headache was still present and continued whilst he was in London for a few days. He then drove back again to Lincolnshire. On his return the headache and vomiting became much worse and he stayed in bed for five days. The exact history of the next few days is rather obscure, but he is sure that on May 20th and following days he was much better and going about.

Up to this point the history is not dissimilar to that of some of the slighter cases of subarachnoid hæmorrhage recorded above, except that there was a definite trauma, in the form of a blow, possibly sufficient to have caused actual bruising of the meninges.

On May 30th, that is 19 days after the original attack, the symptoms of which had practically disappeared for some days, he began to have severe pain in the back, thought to be lumbago. During the next two days it gradually got worse extending down both legs. On June 2nd he vomited frequently and frontal headache has been more or less constantly present ever since. He walked into my room on June 5th with considerable difficulty, the legs being very stiff. He complains of frequent cramps in the legs and cannot sit down in the ordinary way with the knees flexed, but has to stretch his legs straight out in front of him on account of the pain. He looked ill, but there were no abnormal physical signs above the legs. There were greatly exaggerated knee-jerks and well-marked Kernig's sign. In one foot there was a doubtful toe extension. No sensory changes; no sphincter trouble.

He was admitted to a nursing home, and in my absence Dr. Skinner kindly took charge for the next 24 hours. Lumbar puncture on the same evening showed no increased pressure, but the first sample of about 10 c.cm. was almost black, the second a deep red, and the third distinctly blood stained. None of the specimens showed any clot after standing an hour. A few hours after the removal of 30 c.cm. of cerebro-spinal fluid the pains in the back and legs became definitely less; and during the next few days disappeared together with Kernig's sign. On June 16th a second lumbar puncture gave primrose yellow colour, with no increase of pressure. He was kept in bed for some weeks and made a steady and uneventful improvement. In July he was practically convalescent. I saw him again about a year later when he was perfectly well in every way.

The complete data for an exact reconstruction of the events in this case are wanting. Whether or not there was a subarachnoid hæmorrhage following the blow on May 12th must remain uncertain. The symptoms and course are consistent with such a view, but unfortunately lumbar puncture was not done. At any rate, whatever it had been, the immediate effects had passed off by May 25th, for he was then and for the next few days going about and felt quite well. It seems clear therefore that the blood found in the spinal theca on June 5th was not there during those days, and that it did not begin until May 30th when the lumbar pain first made its appearance. The condition of the cerebro-spinal fluid on June 5th, which was still definitely red in colour, is consistent with this. Judged by Froin's findings it would be "red" with a hæmorrhage seven days before, but not with one three or four weeks old. On this assumption, everything points to the seat of this bleeding as intraspinal rather than intracranial, and distinct from the original one following the blow. The complete absence of head symptoms at the onset of the lumbar pain supports this. The headache and vomiting which followed in a day or two would be due to the general irritation of the meninges. If this explanation of his illness is correct, it suggests that this man has some tendency to spontaneous meningeal bleeding not limited to one place, and therefore probably not a "leaking aneurysm." This is supported rather strikingly by his previous history. He says that on quite a number of occasions when playing Rugby football he had been knocked out, suffering from concussion and being laid up in bed for some days with head symptoms. Also that following a motor-cycle accident a few years e was diagnosed as having a fractured base. l, his family were so used to his severe head oms after an injury that they were not unduly ed at the effect of the boxing knock-out in nd did not pay special attention to it.

ntaneous subarachnoid hæmorrhage of intra- origin is very much more rare than intra- l. It does occur from time to time. Michon[8] s two cases and gives an account of some of previously recorded. Amongst these, one of bears some resemblance to my case. This was led by Rénault and Foix.[9] A man, aged 25, suddenly with severe pains in the back and ke double sciatica. On the tenth day the pains still present, together with stiffness and weakness e legs, Kernig's sign, headache, and slight fever. ar puncture on the twelfth day showed blood- d fluid and relieved the pain. He made a lete recovery.

Treatment.

e treatment of subarachnoid hæmorrhage is sarily similar to that of other deep-seated ings which cannot be directly reached. There however, special circumstances arising from its ty which call for certain modifications. In ningeal hæmorrhage, the danger is not of syncope excessive loss of blood, but of fatal intracranial ure from a comparatively small amount. Thus, t absolute rest in bed is essential, it is not sary for the patient to be laid flat, indeed it is r that he should be propped up more or less ding to whatever position he finds most comfort- Whether conscious or unconscious, a free return ood from the head is of primary importance.

regards movements likely to be harmful. The nt will probably not move his head much because ne pain or vertigo which it causes. The other ular movements likely to be most harmful are acts of sneezing, coughing, vomiting, straining. ar as coughing and straining at stool are concerned, should be prevented or controlled by ordinary le measures.

hilst no unreasonable restrictions should be placed hanging the position of the limbs and trunk from e to time, actual getting out of bed under any umstances must be absolutely forbidden. This tment should be continued for the first few days only relaxed in stringency very gradually, vided no further symptoms arise.

umbar puncture is always indicated for the purpose diagnosis, and to relieve the pressure if raised. to whether this should be repeated for purposes of tment, and, if so, how often, there are differences opinion. Some whose views must carry weight ocate repeated puncture at frequent intervals order to remove as much of the effused blood as sible. Others consider that repeated puncture is only uncalled for, but may be actually harmful disturbing the conditions at the seat of hæmor- ge, and even endangering further bleeding. Seeing distance of the site of lumbar puncture from the t of bleeding in the skull, and the nature of the necting channels, such a danger seems remote. ainst repeated puncture as treatment is the comfort and disturbance that it causes, and the t that many cases recover without it. Most of se cases used to recover before lumbar puncture s heard of. Indeed, that is the very reason why eir true nature was not recognised.

Of the seven cases here recorded, six recovered mpletely without repeated lumbar puncture. In ree it was not done until after the acute symptoms were over, whilst in two it was not done at all. One of the latter died. That he would have recovered had repeated lumbar puncture been used seems highly improbable seeing the severe and extensive damage found at autopsy.

In any individual case the question of death or recovery depends largely on whether the bleeding point is capable of firm closure or not, and this in turn depends on its size and surroundings. These cannot be known during life. My view is that, provided the patient is kept at rest, and lumbar puncture is done at the onset for diagnostic purposes, and incidentally to a sufficient extent to relieve any increased pressure at the time, it is unnecessary to expose the patient to the discomfort of repeated punctures, unless the pressure symptoms persist or get markedly worse. As we have seen, slight exacerbations may occur from time to time, as in Cases 2 and 3, but are probably not due to further bleeding, and disappear when left alone.

CARDIAC IRREGULARITIES DURING CHLOROFORM ANÆSTHESIA.

By Ian G. W. Hill, M.B., M.R.C.P. Edin.,

SHAW MACFIE LANG FELLOW IN THE UNIVERSITY OF EDINBURGH.

Soon after its introduction as an anæsthetic it was recognised that the use of chloroform was attended by some danger, and that fatalities were apt to occur from its administration. As long ago as 1858, in an analysis of a series of 50 cases of death under this anæsthetic, Snow[1] pointed out the special danger of "paralysis of the heart" occurring in the early stages of the administration. Since then numerous workers have confirmed and amplified these early observations, and in particular the work of Goodman Levy has thrown much light on the mechanism underlying the cardiac arrest in these cases.

Levy[2, 5] showed that in the cat, under low percentages of chloroform vapour, gross disturbances of heart action were common. These took the form of multiple ventricular extrasystoles, appearing in large numbers and arising from many foci. They tended to disappear with deepening anæsthesia, but when they were present it was comparatively easy to produce fatal ventricular fibrillation by any one of a number of factors. Stimulation of a sensory nerve, struggling by the animal, and administration of nicotine all favoured the onset of fibrillation, but most fatal of all was the administration during the anæsthesia of small doses of adrenaline.

When fatal cardiac arrest in man occurs under chloroform, its onset is frequently during the first few minutes of the inhalation: it is associated with struggling, and with light anæsthesia rather than with overdosage. It is also specially apt to follow administration of adrenaline.[6] It has been argued that such features point to the occurrence in man of the same ventricular fibrillation that Levy found to be so common a cause of death in the cat. There has never been complete conviction, however, that the results obtained from work on such an animal as the cat could be transferred *in toto* to man. Gill, for example, in a discussion on one of Levy's papers,[2] contrasts the effects of section of the vagus nerve in man and animals. The present position is probably accurately expressed by Parade [7] in a recent paper: "The conclusion is hardly to be doubted that in chloroform death ventricular fibrillation is involved, though the certain electrocardiographic evidence for man is lacking."

The results presented in this paper are the outcome of an attempt to follow electrocardiographically the effects on the heart of chloroform administration in man. While such observations under ether or gas and oxygen are comparatively common in the literature, I can find but four previously published reports on comparable studies in chloroform cases.

The earliest of these was a case reported by Ritchie [8] [9] in 1912, where records were taken by polygraph from a man of 19 years undergoing operation for femoral osteomyelitis. Thirty minutes after induction the pulse-rate rose to 227 per minute, and the jugular tracing showed waves at double that figure. This attack of probable auricular flutter gave way in three minutes to auricular fibrillation, and two minutes later there was return to normal rhythm at 125 per minute. Further progress was uneventful.

In a second case, reported by Hecht and Nobel [10] in 1913, ten electrocardiograms were taken from a girl of 6 years undergoing operation for mastoid suppuration. The operation lasted 30 minutes, and anæsthesia throughout was by chloroform. Beyond slight slowing of the rate, no change whatever was noted in the records.

The third reference is to a series of cases reported by Cluzet and Tixier [11] in 1919, of which six were under chloroform anæsthesia, all young and without heart disease. In all, marked cardiac slowing, even to half the original rate, was noted. In two cases there were frequent extrasystoles, negative in lead II. There was usually a slight diminution in the height of the "three main waves" of the electrocardiogram (? P.R.T., or ? R.S.T.). In their summary, the authors state that chloroform in the stage of muscular relaxation produces cardiac slowing and sometimes extrasystoles, but none of the serious electrocardiographic disturbances observed in the dog. (The changes referred to in the dog were described by Cluzet and Petzetakis [12] as "of the nature of heart-block, with pauses as in Stokes-Adams disease.")

Lastly, Unger and May,[13] in a paper dealing with avertin anæsthesia, refer to one case where chloroform was used. As no mention is made of any abnormality in the records, one may conclude that disturbances were absent.

It will be noted that in none of these papers is any light thrown on the interesting question of the behaviour of the heart during early induction.

MATERIAL AND METHODS.

Electrocardiograms have been taken in a series of 41 patients* undergoing major surgical operations. Thirty-seven of the cases were under general anæsthesia, chloroform being employed in 17. Though chloroform was only used throughout the operation in a few of these, in 16 the cardiac mechanism during the induction period under this anæsthetic was studied by string galvanometer. The other anæsthetics employed were ether, gas and oxygen, ethyl chloride, avertin, and in a few cases spinal anæsthesia or local infiltration with novocain. The ages of the patients in the chloroform group varied from 11 to 66 years, the majority, however, being about 60 (actual ages: 11, 15, 18, 25, 38, 38, 55, 56, 59, 59, 61, 62, 63, 63, 64, 65, 66). With one exception, all these patients, after a full clinical examination, were considered to have normal cardiovascular systems. The exception was a man of 65 years, with a history of palpitation, a slightly enlarged heart, and raised blood pressure (150/90 mm. Hg). The high average age of this group is due to the type of operation involved. Induction with chloroform is seldom used in these wards except as a preliminary to intratracheal ether, the anæsthetic of choice in such operations as excision of cervical lymph glands. It follows that practically all the chloroform cases were patients with enlarged cervical lymph glands, generally malignant, and the average age of the patients was therefore high.

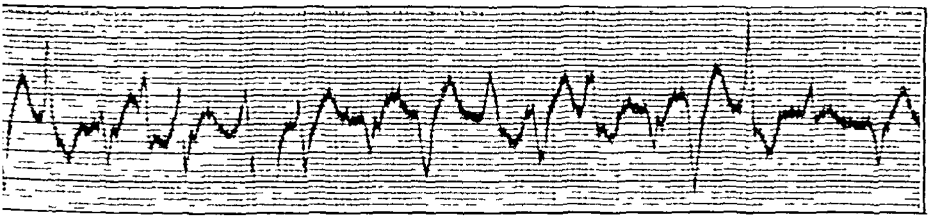
The electrodes—silver plates, 6 in. × 1½ in., coated with silver chloride in the electrolytic bath—were bound to the patients' limbs with lint pads soaked in saline. Usually all three leads were available. Connexions to the string galvanometer about 150 yards from the operating theatre were by overhead wires; signals and telephone circuits were separately wired. Resistances generally were low, and little interference from extraneous currents was experienced. In the majority of cases the electrodes were applied and control records taken while the patient lay in the ante-theatre, before induction was started. The electrodes were left on throughout operation, and the fibre of the electrocardiograph was under constant observation. Records were taken at frequent intervals, and at once if changes in rate or rhythm were observed. Special points in the operative technique were indicated by signal, and records were taken during manipulation of viscera.

SUMMARY OF RESULTS.

The chloroform results only will be considered here, the results of the whole series being dealt with in greater detail elsewhere. The induction period with chloroform was observed or recorded 16 times. Of these, three cases showed no abnormality in the records, while three others showed merely minor alterations, such as bradycardia, or abolition of the P waves. In one case the rate increased from 115 to 160 per minute during induction, a sinus tachycardia without other change. In one other case the control records showed numerous ventricular extrasystoles, and records during induction and later in anæsthesia showed little change. But in the remaining eight cases, seven of whom had previously yielded physiological control records, marked disturbances appeared. One case, a boy of 18 with healthy cardiovascular system, developed marked sinus arrhythmia, with disappearance of P waves during the slow periods. This condition developed 12 minutes after the start of the administration, and lasted less than half a minute. It did not recur, and was not attended by any signs of clinical importance. In seven cases gross disturbances arose in the form of multiple ventricular extrasystoles. These varied in number from an occasional ectopic beat to as many as 146 in two minutes, and arose in some cases from many in both ventricles. Bigeminal and trigeminal is of coupling were common, and on occasion ı bizarre records as that figured (see Figure) ; obtained. In six of the cases the extrasystoles e during induction, in five spontaneously, and in after intentional vagal stimulation (carotoil pressure). In one case the appearance of asystoles was delayed until full surgical anæsthesia been reached, and in this case they recurred half an hour; but here there was definite piratory embarrassment. In all the others their earance was transient, and after a period of l disorder the heart settled, with deepening sthesia, to a normal sequential rhythm. The earance of extrasystoles in large numbers was netimes associated with struggling. It is notethy that *in none of these cases did the condition* the patient give rise to alarm. The pulse-rate certainly raised, but the colour and condition ained satisfactory, and administration of the esthetic continued quietly.

---

* The cases observed were patients in the clinic of Prof. D. P. D. Wilkie, to whom I am indebted not only for permission to publish these records, but also for the facilities afforded me throughout in his wards and theatre. The records were made in the electrocardiographic department of the Clinical Laboratory, also in the Royal Infirmary, Edinburgh.



ctrocardiogram, lead II. Male aged 66. Record taken after seven minutes' chloroform administration. "Multiple ventricular tachycardia": rate 150 per minute.

In the patient known to have mild cardiac disease, picture was further complicated by several roxysms of tachycardia at a very high rate (230 r minute). These were electrocardiographically supraventricular origin, and on their subsidence e slower sinus rhythm was disturbed by the stomary bursts of ventricular extrasystoles. In is case also the patient's clinical condition remained tisfactory, and deepening anæsthesia abolished e irregularities.

No comparable disturbances were noted under any the other anæsthetics. With ether and gas and ygen dislocation of the cardiac pace-maker, with iriations in the P waves and shortening of the P–R terval, were found, as reported by other authors, it changes analogous to those under chloroform ere absent. Two cases under avertin, however, iowed more marked disturbances; in both, frequent entricular extrasystoles occurred, with lengthening P–R in one case, and variation in the Q R S omplexes in the other.

DISCUSSION.

Frommel[14] has noted coupled rhythm due to entricular extrasystoles in the guinea-pig during iduction with ether, and Wachsmuth and Eismayer[15] escribe two cases in man where, under ethyl chloride nd ether, multiple extrasystoles appeared, in one ase during induction and in the other during recovery rom the anæsthetic. Chloroform therefore is not lone in producing such extrasystoles. But though iot unique, chloroform appears to be much the most otent anæsthetic in causing these cardiac disurbances. Comparison of the results obtained from nan with Levy's results from the cat shows the close orrespondence between them. The nature of the disurbances, their relation to induction and struggling, their transient nature and disappearance with deepening narcosis, all are similar.

The absence of clinical signs of failing circulation during the cardiac irregularities is at first sight surprising, but can readily be explained. Levy[16] has shown *that in animals* the blood pressure is well maintained during the period of complex ventricular tachycardia, and falls only with the onset of ventricular fibrillation. Collapse of the patient therefore is to be expected clinically only when the latter most grave condition has developed. Further, our tracings show that each extrasystole tends to be only slightly premature, forestalling the rhythmic sinus beat by 1/25th second or thereabouts; the pulse therefore is not noticeably irregular, and the full diastolic filling permitted to the heart allows the extrasystolic beat to discharge a volume of blood equal to a normal systole. This regularity and the well-sustained blood pressure may mislead the observer entirely as to the true cardiac condition of the patient, for there may be present the "multiple ventricular tachycardia" that is so regularly a precursor of fibrillation in animals.

Levy,[3] in discussing the relation of the ventricular tachycardia to fibrillation, states that:

> "Pending further light on this point it is possible to make the important statement that in every single instance of ventricular fibrillation induced by any of the methods I have employed, it has been preceded by a stage of complex ventricular irregularities, and that unquestionably the one condition leads on to the other, whatever their relationship may be. This observation is limited for the moment to conditions in which the heart is affected by chloroform,"

but he is careful to emphasise that not all cases of multiple ventricular tachycardia end in fibrillation. The tachycardia in cats may persist a considerable time and may then revert to normal rhythm, or "on occasion and on occasion only" may terminate in ventricular fibrillation.

The present records demonstrate the occurrence of this "pre-fibrillation phase" in man; it is a matter of good fortune that the graver disturbances did not occur in any case of the series. Since multiple ventricular tachycardia occurs in approximately 50 per cent. of cases anæsthetised with chloroform, it is easy to understand why the fatality-rate under this anæsthetic is so high. It must be emphasised that this stage of complex ventricular irregularity is not in itself serious or dangerous to the patient; its importance lies in the ease with which it may lead to fatal ventricular fibrillation. It is apparent that, *other things being equal, induction* with such an anæsthetic as gas and oxygen, which in our experience does not produce this condition, must be safer than induction with chloroform, which commonly does.

CONCLUSIONS.

Disturbances of cardiac action which generally elude clinical observation can be detected electrocardiographically during chloroform anæsthesia. They occur in about 50 per cent. of cases, and are of the nature of multiple ventricular extrasystoles. These on occasion may be very numerous, and the condition then resembles the "multiple ventricular tachycardia" so characteristically found in the cat, and well known as a precursor of fatal ventricular fibrillation. The danger of chloroform for induction probably lies in its tendency to produce these disturbances.

such features point to the occurrence in man of the same ventricular fibrillation that Levy found to be so common a cause of death in the cat. There has never been complete conviction, however, that the results obtained from work on such an animal as the cat could be transferred *in toto* to man. Gill, for example, in a discussion on one of Levy's papers,[2] contrasts the effects of section of the vagus nerve in man and animals. The present position is probably accurately expressed by Parade[7] in a recent paper: "The conclusion is hardly to be doubted that in chloroform death ventricular fibrillation is involved, though the certain electrocardiographic evidence for man is lacking."

The results presented in this paper are the outcome of an attempt to follow electrocardiographically the effects on the heart of chloroform administration in man. * The cases observed were patients in the clinic of Prof. D. P. D. Wilkie, to whom I am indebted not only for permission to publish these records, but also for the facilities afforded me throughout in his wards and theatre. The records were made in the electrocardiographic department of the Clinical Laboratory, also in the Royal Infirmary, Edinburgh.

ectrocardiogram, lead II. Male aged 66. Record taken after seven minutes' chloroform administration. "Multiple ventricular tachycardia": rate 150 per minute.

In the patient known to have mild cardiac disease, e picture was further complicated by several roxysms of tachycardia at a very high rate (230 er minute). These were electrocardiographically f supraventricular origin, and on their subsidence he slower sinus rhythm was disturbed by the ustomary bursts of ventricular extrasystoles. In his case also the patient's clinical condition remained atisfactory, and deepening anæsthesia abolished he irregularities.

No comparable disturbances were noted under any f the other anæsthetics. With ether and gas and xygen dislocation of the cardiac pace-maker, with ariations in the P waves and shortening of the P–R nterval, were found, as reported by other authors, ut changes analogous to those under chloroform vere absent. Two cases under avertin, however, howed more marked disturbances; in both, frequent ventricular extrasystoles occurred, with lengthening f P–R in one case, and variation in the Q R S omplexes in the other.

DISCUSSION.

Frommel[14] has noted coupled rhythm due to ventricular extrasystoles in the guinea-pig during induction with ether, and Wachsmuth and Eismayer[15] describe two cases in man where, under ethyl chloride and ether, multiple extrasystoles appeared, in one case during induction and in the other during recovery from the anæsthetic. Chloroform therefore is not alone in producing such extrasystoles. But though not unique, chloroform appears to be much the most potent anæsthetic in causing these cardiac disturbances. Comparison of the results obtained from man with Levy's results from the cat shows the close correspondence between them. The nature of the disturbances, their relation to induction and struggling, their transient nature and disappearance with deepening narcosis, all are similar.

The absence of clinical signs of failing circulation during the cardiac irregularities is at first sight surprising, but can readily be explained. Levy[16] has shown that in animals the blood pressure is well maintained during the period of complex ventricular tachycardia, and falls only with the onset of ventricular fibrillation. Collapse of the patient therefore is to be expected clinically only when the latter most grave condition has developed. Further, our tracings show that each extrasystole tends to be only slightly premature, forestalling the rhythmic sinus beat by 1/25th second or thereabouts; the pulse therefore is not noticeably irregular, and the full diastolic filling permitted to the heart allows the extrasystolic beat to discharge a volume of blood equal to a normal systole. This regularity and the well-sustained blood pressure may mislead the observer entirely as to the true cardiac condition of the patient, for there may be present the "multiple ventricular tachycardia" that is so regularly a precursor of fibrillation in animals.

Levy,[3] in discussing the relation of the ventricular tachycardia to fibrillation, states that:

> "Pending further light on this point it is possible to make the important statement that in every single instance of ventricular fibrillation induced by any of the methods I have employed, it has been preceded by a stage of complex ventricular irregularities, and that unquestionably the one condition leads on to the other, whatever their relationship may be. This observation is limited for the moment to conditions in which the heart is affected by chloroform,"

but he is careful to emphasise that not all cases of multiple ventricular tachycardia end in fibrillation. The tachycardia in cats may persist a considerable time and may then revert to normal rhythm, or "on occasion and on occasion only" may terminate in ventricular fibrillation.

The present records demonstrate the occurrence of this "pre-fibrillation phase" in man; it is a matter of good fortune that the graver disturbances did not occur in any case of the series. Since multiple ventricular tachycardia occurs in approximately 50 per cent. of cases anæsthetised with chloroform, it is easy to understand why the fatality-rate under this anæsthetic is so high. It must be emphasised that this stage of complex ventricular irregularity is not in itself serious or dangerous to the patient; its importance lies in the ease with which it may lead to fatal ventricular fibrillation. It is apparent that, other things being equal, induction with such an anæsthetic as gas and oxygen, which in our experience does not produce this condition, must be safer than induction with chloroform, which commonly does.

CONCLUSIONS.

Disturbances of cardiac action which generally elude clinical observation can be detected electrocardiographically during chloroform anæsthesia. They occur in about 50 per cent. of cases, and are of the nature of multiple ventricular extrasystoles. These on occasion may be very numerous, and the condition then resembles the "multiple ventricular tachycardia" so characteristically found in the cat, and well known as a precursor of fatal ventricular fibrillation. The danger of chloroform for induction probably lies in its tendency to produce these disturbances.

This work was performed under the tenure of the Shaw Macfie Lang Fellowship of the University of Edinburgh. The expenses were in part defrayed by a grant from the Moray Endowment Fund.

ADDITIONAL FACTORS IN THE TREATMENT OF LATE RICKETS AND OSTEOMALACIA.*

By Dagmar Curjel Wilson, M.D. Glasg., D.P.H.,
WOMEN'S MEDICAL SERVICE, INDIA (RETD.).

Introduction.—The incidence of late rickets and osteomalacia in northern India has been described, and it has been shown that in urban areas many patients live under social conditions which do not admit of adequate diet or sunlight, while in rural areas field-workers suffering from late rickets and osteomalacia, though obtaining sufficient sunlight, are not in an economic position to obtain an adequate diet.[1] All such cases need vitamin D as calcifying substance, and in its absence utilisation of calcium and phosphorus is impaired; in view of the very small amount of vitamin D often available it is necessary to ensure adequate intake of these minerals.

ADMINISTRATION OF CALCIUM PHOSPHATE.

Examination of the blood chemistry of cases of osteomalacia and late rickets in India has shown a low serum inorganic phosphorus which may be associated with a low serum calcium and tetany.[2]

The conclusion to be drawn from the data summarised in Table I. is that in field-workers living on a diet relatively deficient in vitamins A, D, and salts, the addition of calcium phosphate in doses of 1 drachm daily over a period of six weeks will cure or much improve the pain and deformity of late rickets and osteomalacia. (It has not yet been determined whether calcium or phosphorus is the preponderating missing factor in such cases.) But this treatment is unsuitable for crippled cases, whose condition does not permit of muscular and circulatory activity, or for those patients who are deficient both in diet and sunlight. (The persistence of tetany in some cases also shows that calcium is not made available for use in the body under these conditions.) In such cases the addition of vitamin D is also necessary for cure.

ANTIRACHITIC VALUE OF SUN-IRRADIATED YEAST.

The usefulness of the administration of dried baker's yeast (*Saccharomyces cerevisiæ*), after irradiation by ultra-violet rays in the treatment of various forms of rickets has been recorded by various observers in Europe and America.[3] In order to overcome the cost of imported yeast, and the difficulty attendant on its ultra-violet irradiation in India, the present communication describes the results of treatment with a dried yeast powder prepared in India from the various varieties of yeast left over in distillery vats after fermentation,† and irradiated for eight hours in direct sunlight.

Clinical and Laboratory Notes

EFFECTIVE COUNTERACTION OF AVERTIN NARCOSIS.

BY WALTER P. KENNEDY, PH.D., L.R.C.P. EDIN.,
BEIT MEMORIAL RESEARCH FELLOW.

ONE of the main criticisms of the use of avertin as a basal anæsthetic is that owing to its rectal administration in one dose, empirically determined from the body-weight of the patient, it is not possible to control the further course of its action. The rapid absorption of the substance renders lavage of the rectum of no avail should it be desired to interrupt the anæsthesia. Naturally the first investigators directed their attention to the questions of antidotes and detoxication, and early experiments indicated that the administration of glucose or glycuronic acid might possibly prove effective, but this hope was not realised. Then acceleration of detoxication by means of thyroxin was attempted, and although preparatory administration of the hormone lessened the duration of anæsthetic sleep, the amount of the diminution varied considerably. In addition, the thyroxin had to be administered for several days prior to the operation as its effect is only slowly established, and this was sometimes attended with undesirable symptoms. The use of thyroxin in emergency operations, or in a sudden misadventure, complicating avertin anæsthesia, was impossible; and this avenue of detoxication was thus found to be impracticable.

Last year Killian [1] published the results of animal and clinical experiments on the possibility of interrupting avertin narcosis by means of coramine (pyridine-beta-carbonic acid diethylamide), a powerful analeptic, which had already been shown by Uhlmann [2] to have a stimulating effect on heart and circulation, and an even greater effect on respiration, and the central nervous system in the sense of breaking through induced narcosis. Quantitative animal investigations showed that in respiratory failure under large doses of avertin, coramine was superior to 10 per cent. CO_2, and that if small doses of coramine were administered, subsequent exhibition of CO_2 was effective in stimulating respiration though it had previously failed. In man either one or two injections of 2–3 c.cm. coramine intravenously interrupted light anæsthesia immediately, and restored memory right back to the time of administration. The injection must be administered slowly, otherwise transitory hiccough or a tendency to vomit may appear. Intramuscular administration was also effective but slower in its action, the full effect not being attained for 15 or 20 minutes. In all the cases of deep anæsthesia tested, two intramuscular injections of 3 c.cm. coramine solution 50 per cent. (that is double strength) resulted in the rapid awakening of the patient. The toxicity of coramine is very low, and doses very much in excess of these would be required before any ill-effects were produced. Mörl [3] has since confirmed Killian's results and described a case of serious respiratory failure under avertin in which CO_2 was of no avail but where 3 c.cm. coramine intravenously restored the patient immediately. This case was complicated by advanced disease of the lung.

An extensive experience of avertin basal anæsthesia has been gained in this clinic, and the results of 1000 cases have been published (Young [4]). Since this paper appeared a further 350 cases have been added to the series, and in these equal success has been attained. There have been no fatalities which could be ascribed to the anæsthetic. As previously stated, in a number of instances the great fall of blood pressure and coincident considerable rise in the pulse-rate occasioned some misgiving at first, but detailed investigation showed that this had no serious significance, and that the circulatory disturbance could be readily controlled by hypodermic administration of ephedrine. It was remarked that even in these patients who showed the most marked drop in blood pressure the colour remained good. In a small proportion of cases the depression of respiration was more obvious than that of the circulation; breathing grew slower and more shallow, the face becoming cyanosed although an airway was used. The first inhalation of ether often produced a marked and immediate improvement, and 5 per cent. CO_2 in oxygen rapidly relieved those patients who were not restored by ether (Kennedy[5]).

The appearance of Killian's paper suggested an even more useful antidote; he emphasised the superiority of coramine over CO_2, especially when the degree of respiratory failure was advanced. We therefore adopted the procedure outlined by him in a number of cases, using smaller doses, since complete interruption of the anæsthetic was not desired, and found it to be very efficacious.

The usual dose given was 2–3 c.cm. intramuscularly. This was followed by rapid improvement in colour and deepening and acceleration of the depressed respirations. The slack jaw muscles stiffened, and the jaw no longer had to be supported. At the same time the blood pressure rose, and the pulse became slower and stronger. In no case did the dose lessen the anæsthesia to a degree sufficient to interfere with the operation in progress or about to be started. The patients appeared to wake rather earlier than the average, but exact data on this point are not available.

In two cases only was the intravenous route considered necessary. These were as follows.

C. 4/12/31. Just after her return to bed after dilatation and cauterisation of the cervix the patient's respirations suddenly became extremely shallow, and her pulse almost disappeared; her colour was blue-grey. Within one minute 1 c.cm. of coramine was injected intravenously and 2 c.cm. intramuscularly. There was an immediate improvement, and within 20 minutes the respirations and pulse were normal.

B. 22/4/32. Prior to operation, and to the administration of ether, this patient suddenly became cyanosed and respirations failed almost completely. The pulse was thin and rapid. 2 c.cm. of coramine were injected intravenously, and before the second ampoule was completely given a healthy colour returned. 1 c.cm. was then injected intramuscularly to sustain the action. The operation was conducted without further difficulty, but when it was completed approximately 45 minutes after, the respirations were again unsatisfactory, but rapidly improved on the patient's return to bed.

Although the results aimed at in this series were not so pronounced as those aimed at by Killian, in that no attempt was made to restore consciousness rapidly in any of the patients, they confirm his conclusion that coramine is an effective agent in counteracting and interrupting the cardio-respiratory depression of avertin anæsthesia, which very occasionally reaches a point where active measures are necessary to overcome it.

This work was done in Dr. James Young's Gynæcological Clinic, Royal Infirmary of Edinburgh, and in the Physiology Department, Edinburgh University.

A CASE OF MITRAL STENOSIS

FATAL AT TWO YEARS OF AGE.

By H. B. Day, *M.C.*, M.D., F.R.C.P. Lond.,
ASSISTANT PHYSICIAN TO THE ROYAL CHEST HOSPITAL.

This case is reported because the valvular disease was apparently of the acquired type and its progress was observed.

A female child, aged 24 months, was admitted to the Royal Chest Hospital with the following history. The child had been a healthy infant, weighing 8½ lb. at birth. There were no other children in the family; the parents were healthy, though the father had had rheumatic fever. Normal healthy development continued until, at the age of 10 months, the child had an attack of "influenza" complicated by otitis media. After this illness her health was impaired and she ceased to put on weight. In June, 1931, when aged 20 months, she developed rapid breathing and cough. She was taken to Great Ormond-street Hospital in July, and subsequently admitted under Dr. R. S. Frew. I am indebted to that institution for the following notes.

On admission there was some dyspnœa, the face was pale, and examination showed impaired resonance and diminished air entry at the right base. There was some precordial bulging and a loud systolic murmur at the apex, which was within the nipple line. A radiograph showed some consolidation in the right lower lobe. The signs of unresolved pneumonia gradually cleared up and the child was discharged on August 28th. Subsequently she was brought as an out-patient, but during the next month her weight remained stationary at 20 lb.

In October the patient again became very short of breath, with swelling of the legs, and was brought to the Chest Hospital. Examination showed evident heart failure. The cheeks were flushed and the neck veins engorged; the legs were œdematous and the liver enlarged. Respiration was rapid, but on auscultation of the chest the air entry appeared free. There was some precordial bulging, and the heartbeat was forcible, rapid (120) but regular. The apex was in the nipple line and here a diastolic murmur with thrill was present, followed by a short systolic murmur. No systolic murmur was heard at the base; the pulmonary second sound was accentuated. The child was admitted forthwith (Oct. 24th). Examination of the blood showed a leucocytosis of 16,600; the Wassermann reaction was negative.

Five days after a temporary improvement, the temperature began to rise, and signs of pulmonary involvement appeared. A radiogram showed considerable consolidation in the central parts of the right lung with some pleural effusion. The child rapidly lost strength and died on Nov. 5th.

A post-mortem examination was made by Dr. Norah Schuster, pathologist to the hospital, who has contributed the following notes.

On opening the pericardium some patchy fibrosis of the visceral layer was seen. The heart weighed 90 g. The left ventricle was slightly hypertrophied; the right greatly hypertrophied. There were patches of fibrosis on the internal surfaces of both ventricles and the left auricle. The heart valves appeared healthy with the exception of the mitral, which was reduced to a slit aperture with absolutely rigid walls. The papillary muscles were fibrous and contracted; the edges of the valve were rolled over and extremely hard but without calcification. The foramen ovale and ductus arteriosus were closed.

Microscopical examination showed extensive fibrosis under the endocardium of all the chambers, most marked in the left auricle. Fibrosis in the muscle was greatest in the hypertrophied right ventricle, where there was extensive scarring and replacement of muscle by fibrous tissue. There was no cellular infiltration of the interstitial tissue and no Aschoff bodies could be found.

There were 20 oz. of clear fluid in the right pleura, 1 oz. in the left. The lung surfaces were smooth. On section there was some general purulent bronchitis, most evident in an area of consolidation near the root of the right lung. Microscopically this area showed purulent bronchitis and an alveolar exudate containing abundant endothelial cells. There was some thickening of the alveolar walls by cellular infiltration, but in the opinion of Dr. A. E. Naish (who kindly examined the section) it did not conform to the picture of a rheumatic pneumonia.

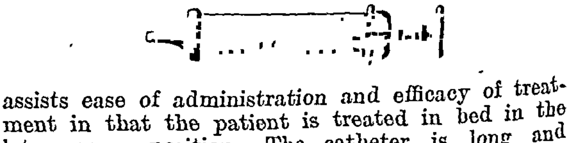
The liver was grossly enlarged and, with the spleen and kidneys, showed the usual appearances of passive congestion.

In this case the healthy condition of the infant for the first eight months of its life and the natural development of the heart in the closure of the foramen ovale seem to negative a congenital malformation. On the other hand, after an acute illness involving the throat, the child ceased to put on weight, and later showed progressive cardiac weakness. An apical systolic murmur was present in the summer and by the late autumn a definite thrill and presystolic murmur had developed. Death was due to progressive mitral stenosis complicated by recurrent inflammation in the lung. These features appear sufficient to justify the conclusion that the mitral disease was of the usual acquired type so common at a later period of life.

NEW INVENTIONS

UTERINE CATHETER.

Intra-uterine medication by glycerin is of service in sapræmia and salpingitis. Several treatments are required, and the instrument here illustrated—a modification of an Eustachian catheter—



assists ease of administration and efficacy of treatment in that the patient is treated in bed in the latero-prone position. The catheter is long and flexible, and after being moulded into a suitable curve is inserted by sight into the uterine cavity, the perineum being retracted by a Sims speculum. It fits an ordinary Record syringe.

Messrs. Allen and Hanburys, London, are the makers.

SECTION OF THERAPEUTICS AND PHARMACOLOGY.

AT a meeting of this section held on May 24th the hair was taken by Dr. E. P. POULTON, the President, nd a discussion on some problems concerning the **revention and Treatment of Acute Rheumatic Infection** vas opened by Dr. W. R. F. COLLIS.

The fundamental treatment of acute rheumatism lepended, he said, on a better understanding of its pidemiology. As a result of study in the special omes for rheumatics the importance had been ealised of the "silent" or "lag" interval of seven to 20 days between the acute throat and the rheumatic relapse; also the infective agent in the throat condition had been proved to be the hæmolytic streptococcus. The child had an acute tonsillitis, completely recovered and lost the streptococci from the throat, and then had a rheumatic manifestation a week or two later. Epidemics associated with other organisms were never followed by rheumatic relapses. If the hæmolytic streptococcus caused acute tonsillitis in non-rheumatic communities, the same syndrome could be observed: tonsillitis, lag period, acute rheumatic fever. There was no difference in ætiology between primary and secondary attacks. Rheumatic patients were very sensitive to hæmolytic streptococcal extract. The first tonsillitic attack sensitised the patient, so that the rheumatic attack was apparently an allergic phenomenon.

These considerations, leading to the conclusion that hæmolytic streptococcal throat infections were an integral part of rheumatic disease, threw open a new field of therapy. In rheumatic homes relapses could be prevented by hygienic measures; ward-swabbing in epidemics, and strict isolation of all cases and of all attendants whose throats harboured the organism; the administration of aspirin during the silent period, and the desensitisation of patients. Overcrowding seemed to be the chief cause of rheumatic fever in communities.

Dr. W. H. BRADLEY said that his own observations on a community of healthy boys showed the disease developing in a non-rheumatic community in exactly the same way as Dr. Collis's had shown relapses to appear in hospitals. The type of streptococcus causing the acute sore-throat was known in some cases to have been absent from the throat a few days before the attack. The condition was a simple hæmolytic streptococcal nasopharyngitis communicated by droplet spread. The school had been free from acute rheumatism for 40 years, though many waves of sore-throat due to other organisms had passed through it. Boys who had previously shown signs of rheumatism relapsed when they came into contact with these epidemics. Acute rheumatism in the general population seemed to be a family disease. The precursor fever would only produce rheumatism in predisposed subjects, and this personal factor might prove amenable to desensitisation. The attack on acute rheumatism should, however, be directed against the original sensitising fever. Continuous doses of aspirin from the onset of nasopharyngitis had value in preventing the subsequent rheumatism, but tonsillectomy was useless. One insulating material was of value above all others in preventing droplet infection—fresh air. Also useful were nasal breathing, clean handkerchiefs, a good diet with plenty of vitamins, warm feet, and a cool head. The pre-rheumatic must not catch cold.

Dr. CAREY COOMBS said that in the city of Bristol the rheumatism rate was very much higher than in the country round. In Bath, very similarly situated only 12 miles away, there was a striking contrast in incidence, possibly associated with the smoke-film over Bristol. A fall in body-weight on return home from hospital had been noticed in the rheumatic patients, even if the home food was adequate. The fall strongly suggested a relapse into a pre-rheumatic condition.

The PRESIDENT commented on the general agreement that acute rheumatism was associated with the hæmolytic streptococcus. Mitral stenosis and carditis could not be explained as allergic phenomena; there must be a stage of invasion as in scarlet fever. He still had a sneaking belief in the value of tonsillectomy; it was definitely useful in nephritis, on which acute rheumatism might supervene. He was rather suspicious of salicylates as being merely symptomatic treatment. He wondered if the advantage of Bath was not its warmth rather than its absence of smoke. The very poor did not get rheumatism because they warmed each other by crowding together.

Dr. F. J. POYNTON said that if there was such a thing as a specific disease, rheumatism in children was an example. It was one of the most specific diseases known. An organism might only develop specificity when it entered certain tissues. He feared that one of the great causes of rheumatism would prove to be sudden change of temperature. There must be a peculiar constitution in acute rheumatism, and he suggested that the individual was born with it, rather than developing a "pre-rheumatic state."

Dr. KINGSTON BARTON said that the deaths from rheumatic fever were much more numerous in the north; warmth had some influence.

Dr. LEONARD FINDLAY had the impression that a different strain of organism caused the arthritic and the choreic types of rheumatism. Tonsillectomy did have some effect, and salicylates were certainly specific in arthritis. He had grave doubts of the causative rôle of the hæmolytic streptococcus.

Dr. E. C. WARNER said that all the rheumatic relapses he had seen had been associated with hæmolytic streptococci in the throat. He wondered whether two different types of organism caused rheumatism and nephritis. The two conditions ran a comparable course, but were seldom associated. Vitamin A had proved not to affect the incidence of rheumatic relapses at all.

Dr. C. W. BRASHER asked for rheumatism figures from other smoky towns.

Dr. B. E. SCHLESINGER said that the environment was still a baffling factor; children often relapsed as soon as they returned from a convalescent home, but they might be well at home and relapse in the country. In some cold climates rheumatism was unknown. Aspirin had been used to try to stop the results of the precedent tonsillar infection, and seemed to have reduced the number of relapses. He doubted the value of tonsillectomy; relapses might be just as virulent after it. The responsible streptococcus need not necessarily hæmolyse blood agar; he had seen a *viridans* infection produce typical attacks. The causal factor might be some part of a streptococcus rather than a type of streptococcus.

Dr. D. H. GEFFEN said that the incidence of rheumatism was much lower on the northern heights were again unsatisfactory, but rapidly improved on the patient's return to bed.

Although the results aimed at in this series were not so pronounced as those aimed at by Killian, in that no attempt was made to restore consciousness rapidly in any of the patients, they confirm his conclusion that coramine is an effective agent in counteracting and interrupting the cardio-respiratory depression of avertin anæsthesia, which very occasionally reaches a point where active measures are necessary to overcome it.

This work was done in Dr. James Young's Gynæcological Clinic, Royal Infirmary of Edinburgh, and in the Physiology Department, Edinburgh University.

A CASE OF MITRAL STENOSIS

FATAL AT TWO YEARS OF AGE.

BY H. B. DAY, *M.C.*, M.D., F.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO THE ROYAL CHEST HOSPITAL.

THIS case is reported because the valvular disease was apparently of the acquired type and its progress was observed.

A female child, aged 24 months, was admitted to the Royal Chest Hospital with the following history. The child had been a healthy infant, weighing 8½ lb. at birth. There were no other children in the family; the parents were healthy, though the father had had rheumatic fever. Normal healthy development continued until, at the age of 10 months, the child had an attack of "influenza" complicated by otitis media. After this illness her health was impaired and she ceased to put on weight. In June, 1931, when aged 20 months, she developed rapid breathing and cough. She was taken to Great Ormond-street Hospital in July, and subsequently admitted under Dr. R. S. Frew. I am indebted to that institution for the following notes.

On admission there was some dyspnœa, the face was pale, and examination showed impaired resonance and diminished air entry at the right base. There was some precordial bulging and a loud systolic murmur at the apex, which was within the nipple line. A radiograph showed some consolidation in the right lower lobe. The signs of unresolved pneumonia gradually cleared up and the child was discharged on August 28th. Subsequently she was brought as an out-patient, but during the next month her weight remained stationary at 20 lb.

In October the patient again became very short of breath, with swelling of the legs, and was brought to the Chest Hospital. Examination showed evident heart failure. The cheeks were flushed and the neck veins engorged; the legs were œdematous and the liver enlarged. Respiration was rapid, but on auscultation of the chest the air entry appeared free. There was some precordial bulging, and the heart-beat was forcible, rapid (120) but regular. The apex was in the nipple line and here a diastolic murmur with thrill was present, followed by a short systolic murmur. No systolic murmur was heard at the base; the pulmonary second sound was accentuated. The child was admitted forthwith (Oct. 24th). Examination of the blood showed a leucocytosis of 16,600; the Wassermann reaction was negative.

Five days after a temporary improvement, the temperature began to rise, and signs of pulmonary involvement appeared. A radiogram showed considerable consolidation in the central parts of the right lung with some pleural effusion. The child rapidly lost strength and died on Nov. 5th.

A post-mortem examination was made by Dr. Norah Schuster, pathologist to the hospital, who has contributed the following notes.

On opening the pericardium some patchy fibrosis of the visceral layer was seen. The heart weighed 90 g. The left ventricle was slightly hypertrophied; the right greatly hypertrophied. There were patches of fibrosis on the internal surfaces of both ventricles and the left auricle. The heart valves appeared healthy with the exception of the mitral, which was reduced to a slit aperture with absolutely rigid walls. The papillary muscles were fibrous and contracted; the edges of the valve were rolled over and extremely hard but without calcification. The foramen ovale and ductus arteriosus were closed.

Microscopical examination showed extensive fibrosis under the endocardium of all the chambers, most marked in the left auricle. Fibrosis in the muscle was greatest in the hypertrophied right ventricle, where there was extensive scarring and replacement of muscle by fibrous tissue. There was no cellular infiltration of the interstitial tissue and no Aschoff bodies could be found.

There were 20 oz. of clear fluid in the right pleura, 1 oz. in the left. The lung surfaces were smooth. On section there was some general purulent bronchitis, most evident in an area of consolidation near the root of the right lung. Microscopically this area showed purulent bronchitis and an alveolar exudate containing abundant endothelial cells. There was some thickening of the alveolar walls by cellular infiltration, but in the opinion of Dr. A. E. Naish (who kindly examined the section) it did not conform to the picture of a rheumatic pneumonia.

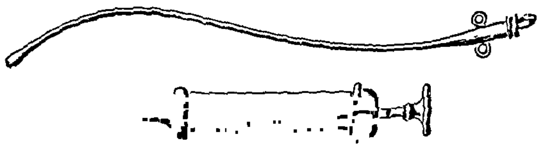
The liver was grossly enlarged and, with the spleen and kidneys, showed the usual appearances of passive congestion.

In this case the healthy condition of the infant for the first eight months of its life and the natural development of the heart in the closure of the foramen ovale seem to negative a congenital malformation. On the other hand, after an acute illness involving the throat, the child ceased to put on weight, and later showed progressive cardiac weakness. An apical systolic murmur was present in the summer and by the late autumn a definite thrill and pre-systolic murmur had developed. Death was due to progressive mitral stenosis complicated by recurrent inflammation in the lung. These features appear sufficient to justify the conclusion that the mitral disease was of the usual acquired type so common at a later period of life.

NEW INVENTIONS

UTERINE CATHETER.

INTRA-UTERINE medication by glycerin is of service in sapræmia and salpingitis. Several treatments are required, and the instrument here illustrated—a modification of an Eustachian catheter—



assists ease of administration and efficacy of treatment in that the patient is treated in bed in the latero-prone position. The catheter is long and flexible, and after being moulded into a suitable curve is inserted by sight into the uterine cavity, the perineum being retracted by a Sims speculum. It fits an ordinary Record syringe.

Messrs. Allen and Hanburys, London, are the makers.

W. MCKIM H. MCCULLAGH,
D.S.O., *M.C.*, F.R.C.S.

of the rectum for cancer when the latter was adherent or involved the vesiculæ seminales in front. Injuries to the ureter were more serious, and they should not occur during a perineal excision; there was, however, a definite risk of injuring the left ureter when carrying out abdomino-perineal excision. If both kidneys were healthy and not infected, he regarded ligature of the ureter as a sound procedure.

In most cases of vesico-colic fistula the best treatment was immediate colostomy.

THE CATHETER HABIT.

Mr. **Lionel Norbury** dealt only with post-operative urinary complications, and vesico-colic fistula. Injury to pelvic nerves, he said, might be a very serious complication in operations for removal of the rectum, but careful handling of the tissues minimised the risk. The difficulty which many patients had in micturition after rectal operations was probably of reflex character; it was quite common after the removal of piles. There was also a difficulty due to catheterisation. The use of a catheter predisposed to infection of the urinary tract, and was the main path by which micro-organisms reached the urethra and the higher portions of the urinary tract. This risk was greater in women than in men. The "catheter habit"—i.e., failure to empty the bladder without the aid of a catheter—was particularly common in women, some of whom had to be re-educated in the matter. A method of preventive treatment, which had greatly reduced the incidence of urinary infection in men, was the use of an indwelling catheter the end of which was sealed by an antiseptic solution. In women infection was largely the result of catheterisation. At the Royal Free Hospital he had had only one case of vesico-colic fistula; as the patient refused operation he did not know whether it was due to diverticulitis or carcinoma.

Dr. **Cuthbert Dukes** said that after a catheter was tied in, three types of infection of the urine might occur. Infection might have taken place either from trauma at the operation, or during the catheterisation, or it might be hæmatogenous in origin. Urinary infections were more common in advanced than in early cases of cancer.

Mr. **E. T. C. Milligan** spoke of the treatment of post-operative urinary fistula. Some urinary fistulæ healed without their cause having been discovered. If the prostate was enlarged it should be removed as soon as the patient was fit for that operation or the fistula was unlikely to heal.

Mr. **G. E. Neligan** called attention to the long time during which some people with vesico-intestinal fistula could live in comparative comfort; in one case the period of comfort was 15 years.

Mr. **John Everidge** spoke of the difficulty of dealing with prostatic retention after some form of colostomy. He commented on the possible value of perurethral prostatic destruction or a method of channelling the prostate, to tide the patient over his period of acute retention, and so enable him to wait until the rectal condition could be dealt with. Cases of prostatic retention associated with carcinoma of the intestine were not very common, but he had recently had such a case, in which a surgeon had done cæcostomy because of acute intestinal obstruction due to growth lower down. Soon after cystoscopy there was acute retention, and the man was found to have an enlarged prostate, and a definite prostatic bar, the existence of which a number of urologists denied. It seemed to be a good case for cauterisation of the prostate, and this succeeded, but the patient died a little later from uræmia.

TUBERCULOSIS ASSOCIATION.

At a meeting of this association, held on May 20th, at the London School of Hygiene, Dr. O. M. **Mistal** (Montana, Switzerland) read a paper on different methods of

Severing Adhesions in Artificial Pneumothorax.

Statistics collected in America and elsewhere showed, he said, the importance of obtaining a complete pneumothorax, but that unfortunately this was not always possible, adhesions interfering with some 75 per cent. of the cases. Various methods of dealing with these adhesions had been tried, among the more popular of which were those of Sauerbruch and Archibald, who severed the adhesions after a double ligature; Paternoster, of Buenos Aires, who resected a part of the eighth rib and freed the adhesions by hand; and that of Jacobaeus under the control of thoracoscopy. The clinical indication for the section of adhesions was when a patient with artificial pneumothorax continued after three to six months to expectorate bacilli and elastic fibres, and to show toxic symptoms. Sometimes the division of only a few small adhesions was sufficient to bring about the disappearance of bacilli. In children, however, the severing of adhesions was often unnecessary, since they stretched by themselves, and the scars were fresh and easy to compress.

The presence of exudates was not necessarily a contra-indication to the operation, unless there was a high degree of fever, or a mixed infection with much albumin. In cases of empyema the operation was possible but dangerous, since it often resulted in fistulas of the chest wall. Tuberculosis of the larynx was not a contra-indication, but nephritis and intestinal tuberculosis were absolute contra-indications. A preliminary radiological examination was essential, but even with this control more adhesions were usually found with the thoracoscope than had previously been suspected, and these might be situated at a different angle than that apparently shown by the X ray. Careful screening of the patient in different positions would obviate many of these errors, especially if the stereoscope was used. Thoracoscopy was the final factor in deciding as to the possibility or advisability of separating the adhesions. Investigation was often especially difficult in pneumothorax cases with a residue of pleurisy, since it was not easy to differentiate between connective and pulmonary tissue. Sounding with a luminous Maurer hook might, however, be of great service.

Maurer grouped adhesions into four classes, Group 1 being composed of adhesions of uniform shape, threads, or cords, which were easy to section. Group 2 consisted of adhesions with an enlarged thoracic insertion, which could also be divided without danger. Group 3, with enlarged and conical pulmonary insertion, were dangerous to cauterise, owing to the risk of opening up cavities. The fourth group was composed of adhesions of hour-glass shape, which had a thoracic insertion of connective tissue and a pulmonary insertion of parenchyma. These adhesions should, of course, be separated in the connective tissue portion.

There were, said Dr. Mistal, various types of thoracoscopes with cautery and lamp carriers. That of Jacobaeus gave an optical deflection of 90°, the modification of this instrument by Unverricht being more luminous and having a larger optical field. With Chandler's thoracoscope, which gave an optical deflection of 30°, orientation was easier. Kremer's thoracoscope gave direct observation of adhesions, without deviation of the optical ray and without transposition, but it could not be used in a small than in other parts of London which were warmer, but which lay under the smoke pall.

Dr. N. GRAY HILL commented on the very small extent to which rheumatism spread in wards or to the nursing staff. There did seem to be some innate predisposition.

The openers briefly replied, Dr. COLLIS remarking that serum was useless and definitely contra-indicated.

SUBSECTION OF PROCTOLOGY AND SECTION OF UROLOGY.

A JOINT meeting of these sections on May 11th, with Mr. W. S. PERRIN, President of the subsection, in the chair, was devoted to the

Urinary Complications of Diseases of the Large Intestine.

Mr. HUGH LETT said that the kidney might show pyelitis or pyelonephritis in many disorders of the large intestine—such as chronic intestinal stasis, colitis, dysentery, diarrhœa, and inflamed hæmorrhoids—while in the pelvis an extension of carcinoma of the rectum might compress one or both ureters. Cystitis, with or without pyelitis, might also be met with in inflammatory conditions of the large intestine. And other conditions, such as cancer or tuberculosis might establish communication between the cæcum, colon, rectum, and bladder. Fissure-in-ano sometimes caused definite pain in the bladder and urethra, and infection of hæmorrhoids had been followed by uncomfortable urinary sensations.

At the London Hospital 172 cases of diverticulitis were admitted in the period 1922–31, and 10 per cent. of these had secondary urinary symptoms. This showed that the incidence of vesical complications was comparatively small; they included disturbance of micturition, *B. coli* cystitis, perivesical abscess, and vesical fistula. Of the six cases of pericystitis, all had been admitted with acute diverticulitis. In none of the six could an abscess be detected. Three of them recovered after medical treatment. The urine was normal in five cases and in the sixth contained red cells and a few leucocytes. Cystoscopic examination was negative. The symptoms in these cases were due to involvement of the bladder wall, the direct result of the extension of the inflammation from the colon. Perivesical abscess if untreated would probably burst into the bladder. An abscess large enough to be detectable above the pubes should be treated by a preliminary incision, followed by drainage.

Vesico-colic fistula was very rare. In the ten years 1922–31, 96,192 patients were admitted into the surgical wards of the London Hospital, and the cases of vesico-colic fistula amounted only to 1 in 10,000 ordinary surgical cases. When it occurred it was usually a symptom of diverticulitis. In malignant disease of the colon fistula was a late development, and the patient was usually so ill that he was admitted to an infirmary. The cystoscopic findings varied. In recent cases of fistula there was an acute general cystitis, with a circumscribed, red, œdematous area. If the fistula had been present some time and the opening was only small, the cystitis gradually became less acute, the œdema disappeared, and was replaced by a small ulcerated area, the rest of the bladder appearing to be normal. Once a vesico-colic fistula was formed, nothing short of colostomy could cure it. Two or three weeks after colostomy, the bladder symptoms rapidly disappeared, and, except for a haze due to bacilluria, the urine became clear. In some cases transverse colostomy was the operation of choice, as in the presence of multiple diverticuli in the descending colon. Colostomy, however, did not always result in a permanent closure of a fistula. When the colostomy was done it was essential to close the distal end of the bowel properly, otherwise leakage might set up reinfection.

Mr. CYRIL NITCH said that urinary complications associated with disease of the large intestine were due to direct involvement of some part of the urinary tract either by spread of inflammation, by adhesion, by invasion of growth, or by a fistula. The kidney was but rarely implicated, owing to its protective barrier of fat and fascia. Bladder symptoms occurred more frequently with diverticulitis of the pelvic colon than with rectal or colic growths. The lymphatics of the cæcum and ascending colon communicate with the lymphatics of the right kidney. A combination of bladder and bowel symptoms was almost pathognomonic of an inflammatory cause. In a series of cases of diverticulitis 50 per cent. had urinary symptoms, whereas in a larger series of carcinoma of rectum and colon only 2·4 per cent. had fistula. The treatment of vesico-colic fistula should be cautious, and in most cases conservative for a considerable time. A preliminary cystoscopy should always be carried out to ascertain the position and size of the opening and its possible cause. If this were found to be intraperitoneal the abdomen was opened and examined carefully with as little disturbance as possible of the pelvic contents. Colostomy should then be carried out mostly in the transverse colon, though in some cases the inguinal operation was preferable. If the fistula was due to a growth considered irremovable, the excision should be carried out as soon as the artificial anus was properly established. If it was due to diverticulitis, however, a year or 18 months should be allowed to elapse before resection was attempted. If normal micturition was not restored after removing the catheter, there were four alternatives: (1) regular catheterisation by the patient or an attendant; (2) removal of obstructing prostatic tissue by perurethral endothermy; (3) permanent drainage by a self-retaining catheter inserted through the bulbous portion of the urethra; (4) (as a last resort) suprapubic drainage.

RETENTION OF URINE.

Mr. J. P. LOCKHART-MUMMERY said the subject covered a wide range of conditions, from retention of urine following the ligation of a pile to the division of a ureter during excision of cancer of the rectum. Retention of urine was a common sequel to this latter operation, which must inevitably cause some injury to the sympathetic nerve-supply of the bladder. He was accustomed to use a retained catheter for some days after the operation, employing Dr. Cuthbert Dukes's apparatus, which enabled the whole catheter area to be bathed in a weak antiseptic. But there was a liability to partial retention after the catheter had been removed, and it was the residual urine which caused infection. The patient should empty the bladder as completely as possible, and it should be regularly washed out. Mr. Lockhart-Mummery had discontinued the use of antiseptics by the mouth. Incontinence following excision of the rectum was very rare; he had had only two cases of nocturnal incontinence after it, both in males, one clearing up in six weeks, the other in two months. Injuries to the urethra after operations on the rectum were also uncommon in his experience; a catheter tied into the bladder and a careful repair of any such injuries with stitches resulted in perfect union. But injuries to the bladder were very likely to occur, either intentionally or accidentally, during excision

EUGENICS SOCIETY.

Voluntary Eugenic Sterilisation.

A CONFERENCE, arranged by the Eugenics Society, was held at the Caxton Hall on May 23rd. At the morning session Sir **ALLAN POWELL** took the chair, and a discussion on the

MEDICAL AND LEGAL ASPECTS

of the subject was opened by Dr. **R. LANGDON-DOWN**. The method of sterilisation proposed by the Eugenics Society, he said, did not affect any essential sex gland or tissue. The operation was simple, especially in the male, and the risks negligible. The legal position was ambiguous at the present time; the operation had been performed in this country by certain practitioners but there was no body of critical experience, and we had to look to America for facts about sterilisation. It was recognised that a well-to-do woman could obtain sterilisation in England, if she wished, but that it was almost impossible for the hospital class of patient to obtain this treatment. The chief methods of preventing the birth of children to defective parents were five: celibacy and abstinence; regulation and restriction of marriage; segregation; and contraception, either temporary, by the use of some appliance; or permanent, by sterilisation. To these might be added abortion and infanticide, more drastic measures which need not come under discussion. Celibacy was obviously restricted to a few persons of foresight and strong character, and could not be relied upon as a general measure. The prohibition of marriage for defective persons did not necessarily prevent propagation. Segregation provided at the present time for one-tenth of the mentally defective persons in the country and it was unlikely that it would ever provide for more than one-quarter. Contraceptive measures were unreliable, and called for a higher degree of intelligence in their use than was commonly found in mentally defective persons. Sterilisation offered a permanent method of contraception. It was not necessary that medical opinion should maintain that defect could be eliminated by this measure in a short time; if it could be shown that sterilisation would reduce this great evil to some extent that was sufficient. Medical opinion was almost unanimous that certain cases of mental deficiency might be prevented by sterilisation, and that no other means were available to reduce heritable mental defect. It was, in any case, undesirable that children should be reared by mentally defective parents.

Sir **THOMAS HORDER** said that sterilisation did not differ from birth control in principle but only in efficiency. Cutting of the human body might be regarded as mutilation, although where an operation was undertaken on behalf of the health of the patient the offence was presumably theoretical, provided reasonable skill and care were shown. Sterilisation was frequently undertaken for women in whom childbearing involved a danger to life. It was conceivable that the husband, in such circumstances, might offer to be sterilised, in order to spare the wife the dangers of the operation. What would be the legal position of the doctor who undertook to sterilise him? Or what would be the legal position of the doctor who sterilised himself? It was not often that a doctor would undertake sterilising operations for reasons other than health, while the legal cover remained so slender. The hospitals, moreover, refused to sterilise patients on eugenic grounds and it was undesirable that there should be a discrepancy between hospital practice and private practice.

PARLIAMENT AND THE LAW.

Wing-Commander **A. W. H. JAMES**, M.P., said that a small non-party committee had been formed in Parliament with a view to introducing a Bill on sterilisation later in the year. In the recent election, when he had stood for an east-midland industrial constituency, he had published his opinion that one of the most pressing needs was to deal with mental defect by means of sterilisation. His view had met with no criticism, but with much expressed support. He had attempted, since entering Parliament, to find out the views of other members, and had analysed those expressed in detailed discussion, or written to him, by 42 members. From 16 he had received unqualified support; from 16 others, personal agreement without any pledge to support a public measure; from 5, non-committal replies; and from 5 unqualified non-acceptance of his principles. He thought it likely that a Bill introduced now would have a two to one majority. The last Bill on sterilisation had been introduced about 18 months ago under the ten minutes rule, and the introducer had begun by saying that it was "probably a long way in advance of public opinion." The opposer had described it as an attempt at class legislation opposed to labour, and its introduction was defeated. He thought that an advance would be made if constituents would bombard their members with letters on the desirability of sterilising mentally defective persons.

Mr. **CECIL BINNEY** said that the law as it affected sterilisation was not simple. Civil proceedings could only be taken against the doctor if he was guilty of breach of contract, for example if he performed the operation against the patient's will, or if he was guilty of negligence. If sterilisation was performed for the benefit of the patient's health it was legal, but there was little doubt that sterilisation of mentally defective persons or persons of unsound mind on eugenic grounds was illegal. The 1861 Act which codified criminal law covered crimes of violence. The consent of the patient would probably be regarded as a defence, under this Act, of a doctor who had performed sterilisation on a person of sound mind. But if the view was taken by the judge and jury that the operation constituted "grievous bodily harm," the consent of the patient would *not* constitute a defence. He was not aware, however, of any express prohibition to self-mutilation. If it was decided that sterilisation was contrary to public policy, then the patient and doctor might be found guilty of conspiracy in consenting to and performing the operation. He thought it would be illegal for a man to be sterilised in order to save his wife from the operation; the law would take the view that he might marry again later. Doctors were unwilling to perform the operation while the state of the law was ambiguous, and it was highly desirable that the law should be made more certain.

STERILISATION IN OTHER COUNTRIES.

Mrs. **C. B. S. HODSON** said that sterilisation of mentally defective persons had been carried out in many American States for about 30 years; she had visited the States in 1928, and had found that, even in the most conservative of them, sterilisation was being carried out on quite a large scale, and was outrunning the legal position. In California defective persons coöperated voluntarily, and were proud of having had the operation performed, regarding it pneumothorax. Adhesions could be cauterised by one of two methods—galvanic or diathermic, the former being the older and the more simple. Absolute asepsis was essential, just as much as in the case of a major operation. The section of adhesions being often very painful, it was necessary to anæsthetise them, this being done by means of long needles. Galvanic cauteries were bent or straight, the former being preferred by Unverricht. When dividing adhesions by the galvano-cautery it was important to cauterise with a red glow which, though acting slowly and emitting smoke, had the advantage of properly coagulating the tissues and preventing hæmorrhage. A white glow irradiated too much heat; it cut rapidly, but exposed the patient to the risk of bleeding. The chief advantages of diathermy were the absence of radiant heat and smoke; the easy and practically painless division of adhesions; and the avoidance of hæmorrhage. The voltage was regulated according to the type of tissue to be sectioned, a weak current being generally used, and a stronger current for old fibrous adhesions. The two methods of cauterisation had each their respective advantages, and many authorities combined them, using galvano-cauterisation after a preliminary diathermic coagulation. Maurer had designed a combined instrument for this purpose.

Complications due to the section of adhesions, though increasingly scarce owing to improvement in technique, included exudate, 30 per cent. of which appeared to be due to hæmorrhage, and could be avoided by working far from the vessels and by coagulating the more vascular strings; emphysema, which was chiefly met with in patients who were coughing a good deal; empyema, which might occur as late as six months after the operation; and symphysis, which could be avoided by timely refills. Many of the failures after cutting adhesions could be avoided by a proper selection of cases, and by undertaking the operation within three months of initiating a pneumothorax.

Atelectasis, Detelectasis, and Apneumatosis.

Dr. ERNEST FLETCHER read a paper with this title. The term "collapse of the lung" was, he said, being used to include so many different conditions with widely differing ætiology, that two new terms had been introduced—detelectasis and apneumatosis. The term detelectasis implied that a lung which had once been inflated was now collapsed or collapsing—differing thus from an atelectatic lung, a term which should only be used with reference to a congenital or fœtal condition of incomplete expansion of the lungs. Detelectatic collapse was nearly always lobar; there was actual falling in of the lobe so that the visceral and parietal layers of the pleura were no longer in contact. The term apneumatosis was used by the speaker to describe a special condition generally due to bronchial obstruction in which the alveoli were comparatively airless, but the elastic tissue of the lung being intact the visceral and parietal layers of the pleura were in their usual relationship.

Atelectatic areas might be either lobar or lobular in distribution. In the lobar type atelectasis led to a considerable reduction in the volume of blood going through the lobe, so that there was little circulation through unaerated blood channels. The final stage of lobar atelectasis was often confused because of a terminal infection in the lung or elsewhere. The symptomatology was either that of the diminishing area available for pulmonary ventilation or that of the terminal infection. The age of the patient varied, the oldest recorded case being 58; and the actual cause of death might be a hæmoptysis. It was evident that if the parenchyma of a lobe was atelectatic, the bronchi supplying the lobe must dilate when they became infected, and this was probably the reason why these conditions had always been labelled bronchiectasis. In the lobular type of atelectasis small areas in various parts of the lung remained permanently uninflated, in the case either of weakly children or of children subjected to unusual stresses. The atelectatic areas in these cases being scattered and in close proximity to fully patent alveoli would receive an almost normal blood-supply, and in consequence a proportion of blood would be returned unaerated from the lungs; the carbon dioxide tension would rise, and the hæmoglobin would be incompletely saturated. Such children therefore suffered from attacks of dyspnœa and cyanosis; and were prone to infection in their early days, so that broncho-pneumonia was a common incident with them. The final stage of lobular atelectasis was probably the condition known as congenital cystic lung. As a rule the case would come to notice either because the cysts pressed on the rest of the lung or because they became infected or led to bronchiectasis.

Detelectasis might be of sudden or gradual onset, the former type including the condition known as "massive collapse," the mechanism of which was still in doubt. Detelectasis of gradual onset usually involved a complete lobe—in the majority of cases the lower lobe. In a recent series of 100 cases of bronchiectasis of the general non-specific type, 20 had atelectatic lobes, 15 of these patients being under 17 years of age. These cases were difficult to diagnose clinically, since they gave no signs except those of the compensatory emphysema which occurred in the other lobes. The X ray was the usual method of diagnosis, the detelectatic lobe being represented by the basal triangular shadow with its hypotenuse running obliquely downwards and outwards from the mediastinum to the radiological periphery of the lung field. Atelectasis of gradual onset was never seen except in cases of gross lung infection, which might or might not be specific. Elastic fibres were never found in the sputum, as they might be in tuberculosis, but as the infection spread through the lung the fibres were involved and became destroyed in situ. Then as the destruction of elastic tissue proceeded the negative pressure fell and gradually the lobe collapsed. In all cases where general detelectasis occurred there was a compensatory emphysema in the other lobes of the same lung, but never, apparently, in the other lung. This was evidently not a central but a peripheral mechanism. X ray photographs showed that gradual detelectasis involved no displacement of the mediastinum, in contrast to the condition found in acute detelectasis where such displacement was one of the classical diagnostic signs.

Apneumatosis.—In this condition there might be either merely impairment of lobe and diminished air entry over the affected lobe, or the classical signs of consolidation might be present, irrespective of the ætiological factor concerned; but depending on the degree of obstruction and the rate at which it had occurred. On the X ray film there was a loss of translucency confined to the lobe concerned, the loss of translucency being seen as far out as the radiological periphery of the lung. Extensive apneumatosis was occasionally seen in connexion with fibroid tuberculosis where the larger bronchi were concerned. Kyphosis and kypho-scoliosis frequently led to apneumatosis because of the kinking of the bronchi.

EUGENICS SOCIETY.

Voluntary Eugenic Sterilisation.

A CONFERENCE, arranged by the Eugenics Society, was held at the Caxton Hall on May 23rd. At the morning session Sir Allan Powell took the chair, and a discussion on the

MEDICAL AND LEGAL ASPECTS

of the subject was opened by Dr. R. Langdon-Down. The method of sterilisation proposed by the Eugenics Society, he said, did not affect any essential sex gland or tissue. The operation was simple, especially in the male, and the risks negligible. The legal position was ambiguous at the present time; the operation had been performed in this country by certain practitioners but there was no body of critical experience, and we had to look to America for facts about sterilisation. It was recognised that a well-to-do woman could obtain sterilisation in England, if she wished, but that it was almost impossible for the hospital class of patient to obtain this treatment. The chief methods of preventing the birth of children to defective parents were five: celibacy and abstinence; regulation and restriction of marriage; segregation; and contraception, either temporary, by the use of some appliance; or permanent, by sterilisation. To these might be added abortion and infanticide, more drastic measures which need not come under discussion. Celibacy was obviously restricted to a few persons of foresight and strong character, and could not be relied upon as a general measure. The prohibition of marriage for defective persons did not necessarily prevent propagation. Segregation provided at the present time for one-tenth of the mentally defective persons in the country and it was unlikely that it would ever provide for more than one-quarter. Contraceptive measures were unreliable, and called for a higher degree of intelligence in their use than was commonly found in mentally defective persons. Sterilisation offered a permanent method of contraception. It was not necessary that medical opinion should maintain that defect could be eliminated by this measure in a short time; if it could be shown that sterilisation would reduce this great evil to some extent that was sufficient. Medical opinion was almost unanimous that certain cases of mental deficiency might be prevented by sterilisation, and that no other means were available to reduce heritable mental defect. It was, in any case, undesirable that children should be reared by mentally defective parents.

Sir Thomas Horder said that sterilisation did not differ from birth control in principle but only in efficiency. Cutting of the human body might be regarded as mutilation, although where an operation was undertaken on behalf of the health of the patient the offence was presumably theoretical, provided reasonable skill and care were shown. Sterilisation was frequently undertaken for women in whom childbearing involved a danger to life. It was conceivable that the husband, in such circumstances, might offer to be sterilised, in order to spare the wife the dangers of the operation. What would be the legal position of the doctor who undertook to sterilise him? Or what would be the legal position of the doctor who sterilised himself? It was not often that a doctor would undertake sterilising operations for reasons other than health, while the legal cover remained so slender. The hospitals, moreover, refused to sterilise patients on eugenic grounds and it was undesirable that there should be a discrepancy between hospital practice and private practice.

PARLIAMENT AND THE LAW.

Wing-Commander A. W. H. James, M.P., said that a small non-party committee had been formed in Parliament with a view to introducing a Bill on sterilisation later in the year. In the recent election, when he had stood for an east-midland industrial constituency, he had published his opinion that one of the most pressing needs was to deal with mental defect by means of sterilisation. His view had met with no criticism, but with much expressed support. He had attempted, since entering Parliament, to find out the views of other members, and had analysed those expressed in detailed discussion, or written to him, by 42 members. From 16 he had received unqualified support; from 16 others, personal agreement without any pledge to support a public measure; from 5, non-committal replies; and from 5 unqualified non-acceptance of his principles. He thought it likely that a Bill introduced now would have a two to one majority. The last Bill on sterilisation had been introduced about 18 months ago under the ten minutes rule, and the introducer had begun by saying that it was "probably a long way in advance of public opinion." The opposer had described it as an attempt at class legislation opposed to labour, and its introduction was defeated. He thought that an advance would be made if constituents would bombard their members with letters on the desirability of sterilising mentally defective persons.

Mr. Cecil Binney said that the law as it affected sterilisation was not simple. Civil proceedings could only be taken against the doctor if he was guilty of breach of contract, for example if he performed the operation against the patient's will, or if he was guilty of negligence. If sterilisation was performed for the benefit of the patient's health it was legal, but there was little doubt that sterilisation of mentally defective persons or persons of unsound mind on eugenic grounds was illegal. The 1861 Act which codified criminal law covered crimes of violence. The consent of the patient would probably be regarded as a defence, under this Act, of a doctor who had performed sterilisation on a person of sound mind. But if the view was taken by the judge and jury that the operation constituted "grievous bodily harm," the consent of the patient would *not* constitute a defence. He was not aware, however, of any express prohibition to self-mutilation. If it was decided that sterilisation was contrary to public policy, then the patient and doctor might be found guilty of conspiracy in consenting to and performing the operation. He thought it would be illegal for a man to be sterilised in order to save his wife from the operation; the law would take the view that he might marry again later. Doctors were unwilling to perform the operation while the state of the law was ambiguous, and it was highly desirable that the law should be made more certain.

STERILISATION IN OTHER COUNTRIES.

Mrs. C. B. S. Hodson said that sterilisation of mentally defective persons had been carried out in many American States for about 30 years; she had visited the States in 1928, and had found that, even in the most conservative of them, sterilisation was being carried out on quite a large scale, and was outrunning the legal position. In California defective persons coöperated voluntarily, and were proud of having had the operation performed, regarding it as something which placed them on the level of the most responsible thinkers in the community. The relatives were also ready to coöperate, and brought children to the institutions voluntarily in order that they might be sterilised. There appeared to be a diminished tendency to promiscuity among those operated on, probably because of careful education in the institutions, and supervision afterwards under a high type of social worker.

Miss **H. Pocock** said that Alberta, Canada, was the only province in the British Empire which had an Act authorising sterilisation of mentally defective persons. This Act became law in 1928, and up to December, 1931, 106 cases had been presented for sterilisation and the operation had been approved by the Board in 101. Sterilisation had been performed on 80 of these up to that time; in the follow-up reports of 32 of them, it was interesting to note that 17 patients had "improved physically and mentally, and with satisfactory adjustment," 13 were physically well with no mental change, and 2 were fair physically and mentally. Recommendations for sterilisation were first made by the head of the mental defective training school; a report was then made by a social worker on the family history and home conditions. The patient was next seen by an independent doctor, and if he agreed with the previous reports, the patient, or those responsible for him, asked for the operation in writing and signed the document before witnesses. This request with the three reports was sent to the Board and then to the Minister of Health. If the case was approved, the operation was performed free of charge. In Michigan, U.S.A., a system of compulsory sterilisation was in force, but, in addition, every attempt was made to secure the coöperation of the patient and his parents.

SOCIAL AND MORAL ASPECTS.

At the afternoon session Prof. **R. Ruggles Gates** took the chair, and the discussion was opened by Prof. **A. M. Carr Saunders**. There was no objection, he said, to sterilisation performed in the interests of health, and therefore it was not the operation itself but its purposes to which objections were raised. There was, however, a moral obligation not to bring defective children into the world. Sterilisation was not proposed as an alternative to segregation but as an adjunct to it. Prohibition of marriage was humiliating, and, besides being ineffective, robbed the defective person of the opportunity of enjoying a stabilising environment. While there was no reason to suppose that sterilisation would increase promiscuity or the spread of venereal disease, it was extremely probable that the prohibition of marriage would augment these evils. It was unlikely that sterilisation would rob the world of persons of talent or genius, for these were rarely born to mentally defective parents.

Dr. **C. J. Bond** said that a movement was going on under the Leicester local health insurance committee to spread information on eugenic marriage. The local body responsible for the welfare of the blind had been reluctant to allow those under their care to marry where there was a danger of transmitting blindness. It had been possible to arrange for the sterilisation of some of these patients, with the result that they had been able to marry. Hospitals were unwilling to give facilities for voluntary sterilisation to their patients, and this operated unfairly as between the rich and the poor. An informed public opinion and a change in the law were needed.

The Rev. **J. C. Pringle** said that the principle of voluntary sterilisation had extended at least through the last three civilisations. For 400 years the marriage service had embraced three distinct reasons for union: to provide an outlet for the sexual impulse; for the procreation of children and their proper nurture; and for "mutual society, help and comfort." In this, it was clear that the sexual impulse was differentiated from the procreation and care of children. The same principles appeared to have obtained in previous civilisations. It might therefore be regarded as socially and morally right to make the best possible adjustment as regards sex, and socially and morally wrong to bring children into the world unless all conditions were favourable to their nurture on the best lines.

Dr. **C. P. Blacker** said that the practical proposals of the Eugenics Society embraced sterilisation for mentally defective persons, mental convalescents, and those suffering from hereditary diseases, disabilities, or defects other than insanity or mental defect. The Bill introduced by Major Church had been limited to mentally defective persons only. It had been estimated that only 5 per cent. of mentally defective persons had mentally defective parents, and the reduction in the incidence of mental deficiency attainable by legalising the sterilisation of this group would therefore be small. To decrease the incidence to any marked extent it would be necessary to include the so-called social problem group among those covered by any change in the law. The legal position with regard to the sterilisation of persons not of unsound mind was not well defined, and it might be possible to popularise the operation for the social problem group, disregarding the state of the law.

In the discussion which followed Dr. **R. A. Clegg** put in a plea for large families. Many distinguished persons, he said, were the seventh or eighth sons of clergymen. He thought it inadvisable to discourage large families.

Dr. **B. Dunlop** thought that the demand should be made for voluntary sterilisation rather than voluntary eugenic sterilisation. If the word "eugenic" was included all those who were not segregated or under observation were excluded.

Dr. **J. Greenwood Wilson** and Councillor Mrs. **E. A. Weston** urged the advantage of getting into touch with town councillors up and down the country, in an attempt to establish an informed public opinion on sterilisation of mentally defective persons.—Other speakers included Mrs. **Neville Rolfe**, Alderman **J. W. Black**, Mrs. **Laski**, Lady **Jones**, and Dr. **K. B. Arkman**.

The Cancer Hospital, Fulham-road.—At the annual meeting on May 13th it was reported that last year 1086 patients were admitted, and that the out-patients numbered 1512, who made over 23,000 attendances. The new building has been completed and furnished; the total cost of all the new works has been approximately £140,000. The radiological department is now in full working order. The treatment of patients by radium has been further extended and the Radium Commission has lent a one-gramme bomb. The London Blood Transfusion Service has given invaluable assistance. As usual, the medical committee received many requests to try "cures" for cancer, and whenever their composition is stated they are carefully and sympathetically considered, and, if necessary, investigation is made. Nothing encouraging has resulted, but one communication has opened up a line of research which may lead to the discovery of useful information. Mr. R. H. Jocelyn Swan, the senior surgeon, said that during the last three years nearly 700 cases had been treated with radium, and that some of the results were astonishing, but the statistics, good as they were, would be greatly improved if only cases could be got in their early stages.

ROYAL INSTITUTE OF PUBLIC HEALTH.

ANNUAL CONFERENCE AT BELFAST.

THE annual conference of the Royal Institute of Public Health was held at Belfast, May 10th to 15th, Lord LONDONDERRY presiding. The meetings were well attended throughout by members of the public as well as by professional workers. A proposal made during the conference was that a Ministry of Health should be established in Northern Ireland.

STATE MEDICINE AND MUNICIPAL HYGIENE.

Opening a discussion on *venereal diseases* as a public health problem, Dr. DAVID LEES (Edinburgh) put the case for compulsory notification and treatment of venereal disease. The almoner system had certainly proved very useful at the Edinburgh Royal Infirmary, since five years ago 50 per cent. of the patients failed to complete their treatment, and last year only 17 per cent. defaulted; the almoners also succeeded in getting relatives of patients to attend. But every day in his work he came across evidence for the need of compulsory treatment. Compulsory notification would help women more than men, for in 60 per cent. of the cases of syphilis among women the victim had contracted the disease without transgressing any social law. Dr. EILEEN HICKEY (Belfast) said that in her experience most of the specimens of blood sent for the Wassermann test came from the gynæcological and ear, nose, and throat departments. In most cases of skin disease, excepting such frank diseases as scabies, and in cases of tumour and heart disease the blood should be examined for syphilis. She was opposed to the segregation of women and children suffering with venereal diseases; they should be placed in general wards.

Clean food.—Lieut.-Colonel T. DUNLOP YOUNG (London) described the careful inspection and cleanly handling of animals and meat in the Argentine destined for this country. During the dressing the carcasses are washed with a spray brush with fresh water; here a bowl of dirty water and a cloth are used time after time. Mr. P. F. DOLAN (chief veterinary inspector, Dublin) referred to the importance of antemortem inspection—a carcass setting well is not always an index of soundness.

Mr. A. M'LEAN (city veterinary surgeon, Belfast) believed that the risk of tuberculous infection of milk would be rendered almost negligible if whole-time veterinary inspectors were appointed to make frequent inspections of the farms and carry out repeated bacteriological examinations. At present the Bovine Tuberculosis Order is administered by part-time officials who are general veterinary practitioners in their districts.

Councillor C. BENNETT (Bethnal Green) referred to the difficulty of enforcing the regulations on the disposal of trade refuse. Although receptacles are now provided by his council for certain stalls, the sides of the roadway were covered with refuse and litter—fish scales, feathers, cabbage leaves, flowers, and rotten fruit. Petri plates of nutrient agar exposed in market streets and incubated showed many colonies, including streptococci and coliform organisms. There were no regulations governing such articles of food as shell-fish and stewed eels prepared for consumption on the spot, sweets, cut fruit, dates, and cakes. Councillor Bennett said that until public opinion could be educated to the point of abolition of the gutter market, food stalls in street markets should be separated from other stalls.

A municipal foot clinic.—Dr. A. T. W. POWELL (Walthamstow) said that at a foot clinic recently set up by his local authority a charge of 1*s.* per attendance was made. The work was carried out by a chiropodist who was also a trained nurse and masseuse. The conditions treated include corns, warts, bunions, ingrowing toenails, dropped arches, inflamed bursæ, minor foot injuries, and rheumatic conditions of the foot. A surprising number of school-children had attended for multiple warts on the soles of the feet, and interdigital ringworm was not uncommon. Foot baths and radiant heat baths were used. A number of patients were referred to an orthopædic surgeon.

INDUSTRIAL HYGIENE.

Sir THOMAS OLIVER spoke of the unsatisfactory *hygienic conditions in the British mercantile marine.* In 1926 30·5 per cent. of the British ships inspected in the port of Manchester were found to be insanitary, against 18·9 per cent. of the Norwegian ships and 17·2 per cent. of the U.S.A. ships. Dr. A. M. CRITCHLEY (West Suffolk) confirmed this view. In most British ships the passengers were the first consideration, then the cargo, and the crew were put into whatever space was left over, with the result that their cabins are small, uncomfortable, and badly ventilated. On the Russian boats there were only two seamen to a cabin, and a recreation room was provided. From a visit to Russia he had found that in some respects industrial hygiene there was in an advanced stage.

The health of chromium plating workers.—Dr. H. B. TRUMPER (medical officer to the Association of British Chromium Depositors) said that chromium plating is an electrolytic process carried on in a special vat filled with a solution of chromic acid, chromates, a small quantity of boric acid and a catalyst, usually chromium sulphate. The deleterious agent in the solution was probably chromic acid, but certain of the ill-effects to workers could also be produced by chromates. The articles to be plated were wired on to a frame, the cathode, and the sharp ends of the wire caused small abrasions of the skin; chrome holes were produced by the action of the chromic acid on the broken skin. Owing to the amount of current used the wire may become hot; burns were liable to be produced on the hands. Nasal ulceration was undoubtedly due to the chromic acid carried up in the spray of hydrogen at the cathode; perforation of the nasal cartilaginous septum when it occurred never healed. Dermatitis due to chromic acid solutions used in plating was comparatively rare; skin changes apart from chrome holes did occur, but Dr. Trumper believed them to be allergic. Iritis was an occasional complication of chrome dermatitis. Vomiting was a symptom to which chromium workers seemed to be liable. Four cases of serious vomiting for which no other cause could be found occurred among a series of 160 persons suffering from chrome poisoning.

Dr. W. E. COOKE (Wigan) described a fatal case of *silico-anthracosis* occurring in a soft-coal miner who during his ordinary work had absorbed sufficient silica to cause lymphatic occlusion. The total silica of the lung-ash was 40·2 per cent. Statistical evidence that coal-miners suffered from pulmonary tuberculosis to a less extent than many other workers had engendered an attitude of complacency towards the mine atmosphere. Not only hard stone dust but all kinds of dust must as far as possible be suppressed.

Occupational dermatitis.—Dr. R. M. B. MACKENNA as something which placed them on the level of the most responsible thinkers in the community. The relatives were also ready to coöperate, and brought children to the institutions voluntarily in order that they might be sterilised. There appeared to be a diminished tendency to promiscuity among those operated on, probably because of careful education in the institutions, and supervision afterwards under a high type of social worker.

Miss H. **Pocock** said that Alberta, Canada, was the only province in the British Empire which had an Act authorising sterilisation of mentally defective persons. This Act became law in 1928, and up to December, 1931, 106 cases had been presented for sterilisation and the operation had been approved by the Board in 101. Sterilisation had been performed on 80 of these up to that time; in the follow-up reports of 32 of them, it was interesting to note that 17 patients had "improved physically and mentally, and with satisfactory adjustment," 13 were physically well with no mental change, and 2 were fair physically and mentally. Recommendations for sterilisation were first made by the head of the mental defective training school; a report was then made by a social worker on the family history and home conditions. The patient was next seen by an independent doctor, and if he agreed with the previous reports, the patient, or those responsible for him, asked for the operation in writing and signed the document before witnesses. This request with the three reports was sent to the Board and then to the Minister of Health. If the case was approved, the operation was performed free of charge. In Michigan, U.S.A., a system of compulsory sterilisation was in force, but, in addition, every attempt was made to secure the coöperation of the patient and his parents.

SOCIAL AND MORAL ASPECTS.

At the afternoon session Prof. R. **Ruggles Gates** took the chair, and the discussion was opened by Prof. A. M. **Carr Saunders**. There was no objection, he said, to sterilisation performed in the interests of health, and therefore it was not the operation itself but its purposes to which objections were raised. There was, however, a moral obligation not to bring defective children into the world. Sterilisation was not proposed as an alternative to segregation but as an adjunct to it. Prohibition of marriage was humiliating, and, besides being ineffective, robbed the defective person of the opportunity of enjoying a stabilising environment. While there was no reason to suppose that sterilisation would increase promiscuity or the spread of venereal disease, it was extremely probable that the prohibition of marriage would augment these evils. It was unlikely that sterilisation would rob the world of persons of talent or genius, for these were rarely born to mentally defective parents.

Dr. C. J. **Bond** said that a movement was going on under the Leicester local health insurance committee to spread information on eugenic marriage. The local body responsible for the welfare of the blind had been reluctant to allow those under their care to marry where there was a danger of transmitting blindness. It had been possible to arrange for the sterilisation of some of these patients, with the result that they had been able to marry. Hospitals were unwilling to give facilities for voluntary sterilisation to their patients, and this operated unfairly as between the rich and the poor. An informed public opinion and a change in the law were needed.

The Rev. J. C. **Pringle** said that the principle of voluntary sterilisation had extended at least through the last three civilisations. For 400 years the marriage service had embraced three distinct reasons for union: to provide an outlet for the sexual impulse; for the procreation of children and their proper nurture; and for "mutual society, help and comfort." In this, it was clear that the sexual impulse was differentiated from the procreation and care of children. The same principles appeared to have obtained in previous civilisations. It might therefore be regarded as socially and morally right to make the best possible adjustment as regards sex, and socially and morally wrong to bring childre into the world unless all conditions were favourabl to their nurture on the best lines.

Dr. C. P. **Blacker** said that the practical proposal of the Eugenics Society embraced sterilisation fo mentally defective persons, mental convalescents and those suffering from hereditary diseases, dis abilities, or defects other than insanity or menta defect. The Bill introduced by Major Church ha been limited to mentally defective persons onl It had been estimated that only 5 per cent. of mentall defective persons had mentally defective parent and the reduction in the incidence of mental deficienc attainable by legalising the sterilisation of this grou would therefore be small. To decrease the incidenc to any marked extent it would be necessary to includ the so-called social problem group among thos covered by any change in the law. The legal positio with regard to the sterilisation of persons not unsound mind was not well defined, and it migl be possible to popularise the operation for tl social problem group, disregarding the state of tl law.

In the discussion which followed Dr. R. A. **Cleg** put in a plea for large families. Many distinguishe persons, he said, were the seventh or eighth sons clergymen. He thought it inadvisable to discoura large families.

Dr. B. **Dunlop** thought that the demand shoul be made for voluntary sterilisation rather tha voluntary eugenic sterilisation. If the word "eugenic was included all those who were not segregated under observation were excluded.

Dr. J. **Greenwood Wilson** and Councillor M E. A. **Weston** urged the advantage of getting in touch with town councillors up and down the countr in an attempt to establish an informed public opini on sterilisation of mentally defective persons.—Oth speakers included Mrs. **Neville Rolfe**, Alderma J. W. **Black**, Mrs. **Laski**, Lady **Jones**, and D K. B. **Arkman**.

The Cancer Hospital, Fulham-road.—At tl annual meeting on May 13th it was reported that la year 1086 patients were admitted, and that the ou patients numbered 1512, who made over 23,000 attendance The new building has been completed and furnished; tl total cost of all the new works has been approximate £140,000. ROYAL INSTITUTE OF PUBLIC HEALTH.

ANNUAL CONFERENCE AT BELFAST.

The annual conference of the Royal Institute of Public Health was held at Belfast, May 10th to 15th, Lord Londonderry presiding. The meetings were well attended throughout by members of the public as well as by professional workers. A proposal made during the conference was that a Ministry of Health should be established in Northern Ireland.

STATE MEDICINE AND MUNICIPAL HYGIENE.

Opening a discussion on *venereal diseases* as a public health problem, Dr. David Lees (Edinburgh) put the case for compulsory notification and treatment of venereal disease. The almoner system had certainly proved very useful at the Edinburgh Royal Infirmary, since five years ago 50 per cent. of the patients failed to complete their treatment, and last year only 17 per cent. defaulted; the almoners also succeeded in getting relatives of patients to attend. But every day in his work he came across evidence for the need of compulsory treatment. Compulsory notification would help women more than men, for in 60 per cent. of the cases of syphilis among women the victim had contracted the disease without transgressing any social law. Dr. Eileen Hickey (Belfast) said that in her experience most of the specimens of blood sent for the Wassermann test came from the gynæcological and ear, nose, and throat departments. In most cases of skin disease, excepting such frank diseases as scabies, and in cases of tumour and heart disease the blood should be examined for syphilis. She was opposed to the segregation of women and children suffering with venereal diseases; they should be placed in general wards.

Clean food.—Lieut.-Colonel T. Dunlop Young (London) described the careful inspection and cleanly handling of animals and meat in the Argentine destined for this country. During the dressing the carcasses are washed with a spray brush with fresh water; here a bowl of dirty water and a cloth are used time after time. Mr. P. F. Dolan (chief veterinary inspector, Dublin) referred to the importance of antemortem inspection—a carcass setting well is not always an index of soundness.

Mr. A. M'Lean (city veterinary surgeon, Belfast) believed that the risk of tuberculous infection of milk would be rendered almost negligible if whole-time veterinary inspectors were appointed to make frequent inspections of the farms and carry out repeated bacteriological examinations. At present the Bovine Tuberculosis Order is administered by part-time officials who are general veterinary practitioners in their districts.

Councillor C. Bennett (Bethnal Green) referred to the difficulty of enforcing the regulations on the disposal of trade refuse. Although receptacles are now provided by his council for certain stalls, the sides of the roadway were covered with refuse and litter—fish scales, feathers, cabbage leaves, flowers, and rotten fruit. Petri plates of nutrient agar exposed in market streets and incubated showed many colonies, including streptococci and coliform organisms. There were no regulations governing such articles of food as shell-fish and stewed eels prepared for consumption on the spot, sweets, cut fruit, dates, and cakes. Councillor Bennett said that until public opinion could be educated to the point of abolition of the gutter market, food stalls in street markets should be separated from other stalls.

A municipal foot clinic.—Dr. A. T. W. Powell (Walthamstow) said that at a foot clinic recently set up by his local authority a charge of 1s. per attendance was made. The work was carried out by a chiropodist who was also a trained nurse and masseuse. The conditions treated include corns, warts, bunions, ingrowing toenails, dropped arches, inflamed bursæ, minor foot injuries, and rheumatic conditions of the foot. A surprising number of schoolchildren had attended for multiple warts on the soles of the feet, and interdigital ringworm was not uncommon. Foot baths and radiant heat baths were used. A number of patients were referred to an orthopædic surgeon.

INDUSTRIAL HYGIENE.

Sir Thomas Oliver spoke of the unsatisfactory *hygienic conditions in the British mercantile marine.* In 1926 30·5 per cent. of the British ships inspected in the port of Manchester were found to be insanitary, against 18·9 per cent. of the Norwegian ships and 17·2 per cent. of the U.S.A. ships. Dr. A. M. Critchley (West Suffolk) confirmed this view. In most British ships the passengers were the first consideration, then the cargo, and the crew were put into whatever space was left over, with the result that their cabins are small, uncomfortable, and badly ventilated. On the Russian boats there were only two seamen to a cabin, and a recreation room was provided. From a visit to Russia he had found that in some respects industrial hygiene there was in an advanced stage.

The health of chromium plating workers.—Dr. H. B. Trumper (medical officer to the Association of British Chromium Depositors) said that chromium plating is an electrolytic process carried on in a special vat filled with a solution of chromic acid, chromates, a small quantity of boric acid and a catalyst, usually chromium sulphate. The deleterious agent in the solution was probably chromic acid, but certain of the ill-effects to workers could also be produced by chromates. The articles to be plated were wired on to a frame, the cathode, and the sharp ends of the wire caused small abrasions of the skin; chrome holes were produced by the action of the chromic acid on the broken skin. Owing to the amount of current used the wire may become hot; burns were liable to be produced on the hands. Nasal ulceration was undoubtedly due to the chromic acid carried up in the spray of hydrogen at the cathode; perforation of the nasal cartilaginous septum when it occurred never healed. Dermatitis due to chromic acid solutions used in plating was comparatively rare; skin changes apart from chrome holes did occur, but Dr. Trumper believed them to be allergic. Iritis was an occasional complication of chrome dermatitis. Vomiting was a symptom to which chromium workers seemed to be liable. Four cases of serious vomiting for which no other cause could be found occurred among a series of 160 persons suffering from chrome poisoning.

Dr. W. E. Cooke (Wigan) described a fatal case of *silico-anthracosis* occurring in a soft-coal miner who during his ordinary work had absorbed sufficient silica to cause lymphatic occlusion. The total silica of the lung-ash was 40·2 per cent. Statistical evidence that coal-miners suffered from pulmonary tuberculosis to a less extent than many other workers had engendered an attitude of complacency towards the mine atmosphere. Not only hard stone dust but all kinds of dust must as far as possible be suppressed.

Occupational dermatitis.—Dr. R. M. B. MacKenna

(Liverpool) referred to the difficulty of stating definitely in courts of law whether the skin trouble from which a workman was suffering was or was not an occupational dermatitis. He agreed with the view that in all cases of dermatitis there is an inherent defect of cellular structure or metabolism of the skin whereby certain irritants readily cause eczematous reactions. A certain time must elapse during which the patient became sensitive to the deleterious agent. The incidence of dermatitis would probably be reduced to a small extent if seborrhœic and hyperidrotic subjects, those with a family history of psoriasis and sufferers with xerodermia and prurigo, were excluded from entering trades such as bakery, confectionery, French polishing, and cement work.

TUBERCULOSIS.

Dr. Jane Walker (Nayland, Suffolk), speaking on the *economic aspects of tuberculosis* stated that both incidence and mortality was increasing in the vast army of 2 million women who were employed as clerks, cashiers, and other occupations involving arduous exertion. Dr. D. A. Powell (Welsh National Memorial Association) said that the disease hardly affected the average married woman. Sir Dawson Bates, M.P. (Minister of Home Affairs, Northern Ireland), stated that in 40 years in the highly industrialised city of Belfast, the death-rate from pulmonary tuberculosis had been reduced to nearly one-fifth; in 1890 it was 4·7 per 1000, and by 1930 it had been reduced to 1 per 1000.

Problems in treatment.—Dr. J. Shaw (Belfast) referred to the findings of Dr. Percy Stocks and Miss M. N. Karn relating to the first 2794 consecutive cases of undoubted pulmonary tuberculosis coming under the survey of the Belfast Tuberculosis Dispensary in the years immediately following 1914. They found that the progress of patients in the early stage treated in sanatoriums was rather worse than that of those treated otherwise; no difference was apparent in the progress of patients in advanced stages in the two groups. Dr. Shaw, however, did not claim that patients would do better at home than in a sanatorium, but that removal to sanatorium should not be a routine measure. He referred to another curious fact. Dr. A. Trimble, when investigating over a period of seven years the fate of children aged 5 years and under living in tuberculous households, found that they did not suffer a death-rate from all causes significantly different from the normal; possibly supervision by the tuberculosis nurse protected them from infection. Dr. R. C. Wingfield (Frimley) put in a plea for turning the tuberculosis service into a purely clinical service, leaving the prevention of tuberculosis to the general public health service.

PATHOLOGY, BACTERIOLOGY, AND BIOCHEMISTRY.

Dr. J. W. Bigger (Dublin) said that in his opinion abortus fever would remain a rare disease in the British Islands. He wished to distinguish between invasions of the human body by the *Brucella abortus* and infections. The organism might pass through the alimentary duct and produce no effect; it might invade the tissues and grow in lymphoid tissues, and although defeated produce agglutinins so that a high titre might be present although the individual has never had the disease; in very rare instances it overcame the resistance and produced infection. The rate in Northern Ireland was 4 cases per million; in the Irish Free State, 0·7; in England and Wales, 0·3; in Denmark and the State of Iowa the figure reached 85 cases per million. In Iowa the majority of isolations of the causative organism from the blood or urine had been of the porcine strain. The only explanation Dr. Bigger could offer of the high prevalence of abortus fever in Denmark, where the bovine type only existed, was that the cows in Denmark must be affected by a strain more virulent to man than those in Great Britain or Ireland. The ideal laboratory method of diagnosis is the cultivation of *Br. abortus* from the blood, urine, or elsewhere, but the comparatively small numbers of successful isolations make it probable that in many cases the organism never gives rise to a septicæmia or bacteræmia and is not present in the urine. Dr. J. S. Baxter (Belfast) pointed out that abortus fever was rare in childhood, the age at which the largest amount of milk was consumed. Dr. Baxter suggested that there were two other possible methods of spread, through insect bites and through carriers.

Dr. G. F. W. Tinsdale (Belfast) gave details of attempts to induce abortus fever experimentally in volunteers. In three cases the ingestion of milk contaminated with 24-hour cultures of porcine strains of *Br. abortus* had no effect, nor did infection result when the dose of milk was repeated after preliminary neutralisation of the gastric juice by a large dose of alkali. Six volunteers were given intravenous doses of *Br. abortus* varying from 20–500 million; the only effect was a temporary rise of temperature. Finally, pyrexia typical of undulant fever with loss of appetite and sweats was produced by the intradermal injection of 20 million of live organisms, suggesting that the commonest method of infection was the contact of the skin with infected material. Dr. W. P. O'Callaghan (Dublin) by testing the blood of 416 pyrexial cases sent for examination in suspected cases of enteric fever had found two which gave agglutination in a titre of 1/2500. On inquiry it was evident that both the patients were cases of abortus fever. From one he isolated the *Br. abortus*. Mr. H. G. Lamont (Ministry of Agriculture, Northern Ireland), when growing the *Br. abortus* from the fœtal calf in cases of infectious abortion in cattle, had found that the pH of the medium must be between 7·5 and 7·8. The acidity of stale milk might account for the infrequency with which the organism was recovered from milk.

VISITS.

Among the visits paid one was to the York Street Flax Spinning Company. The earliest stages of the combing of the flax was carried out by hand by women working in front of hoods provided with exhaust ventilation; notices were put up warning the workers of the danger of contracting tuberculosis if they did not carry out the precautions advised. In the rooms where the flax was combed by machinery exhaust ventilation was also provided. The women and the few men working in the rooms where the narrow flax sliver was passed through hot water in the final stages of its conversion into thread were all barefooted, a precaution against slipping on any oil spilt on the stone floor. High temperature (109° F.) and high humidity were both present in one room where linen was woven and paste used to promote adherence of the threads.

A visit was also paid to the municipal abattoir which was erected shortly before the war. There are now no private slaughter-houses in Belfast, all the owners having been compensated. Three sanitary inspectors who possess the meat certificate act as detention officers, and see practically every carcass opened; the final decision on any doubtful carcass is made by a veterinary inspector.

REVIEWS AND NOTICES OF BOOKS

Recent Advances in Bacteriology and the Study of the Infections.

Second edition. By J. HENRY DIBLE, M.B. Glasg., F.R.C.P. Lond., Professor of Pathology in the University of Liverpool. London: J. and A. Churchill. 1932. Pp. 476. 15s.

THIS has proved, as we anticipated it would, a popular contribution to the Recent Advances series. A second edition has been called for within three years of the first, and a demand was made in 1930 for a Spanish translation. The new edition has been revised and considerably enlarged, over a hundred pages being added. Fresh sections are incorporated on the typhoid-salmonella group and antigenic analysis, on brucella infections, on flocculation tests for syphilis, and on certain diseases due to filtrable viruses such as psittacosis, dengue fever, and sandfly fever, while yellow fever has been transferred from the spirochætal to the filtrable virus infections. Most of these new sections are satisfactory. The antigenic analysis of the salmonella group has been very clearly set forth, and in discussing the modern Widal reaction, with its demand for a much larger series of antigens, the author has maintained a well-balanced attitude, pointing out the advantages both of the old formolised and of the new alcoholised suspensions. In the table on p. 87 a mistake has been made in the structure of *B. paratyphosus* A; the H antigenic factor should be T not I, and according to Bruce White's latest work the somatic factor should be vi not xi. The general account of the filter-passing viruses is perhaps rather below the high level of the rest of the book. Since the publication of the first edition a considerable amount of work has been done on these bodies, tending to bring them more and more into line with the ordinary bacteria, and very little of this work has here been included. In regard to ultra-filtration, no reference is made to any paper later than 1927, no account of Elford's work in this country or of Bechhold's in Germany having been included. The relation of the elementary bodies to the infective agent in variola and fowl-pox, for example, as determined both by ultra-violet microscopy, by staining, and by centrifugal methods is not considered. In the next edition we may hope also for an account of recent work on dog distemper. These omissions are noticeable only because the book is such an excellent one. It is a great feat, in these days when bacteriology is expanding so rapidly, to have produced such an accurate and fair-minded account of its most recent developments.

An Index of Treatment.

Tenth edition. By Various Writers. Edited by ROBERT HUTCHISON, M.D., F.R.C.P., Physician to the London Hospital, and Physician to the Hospital for Sick Children, Great Ormond-street. Bristol: John Wright and Sons, Ltd. 1931. Pp. 1027. 42s.

THE tenth edition of this work is edited by Dr. Robert Hutchison alone, whereas originally the late Mr. H. Stansfield Collier and afterwards Mr. James Sherren were associated with him. Many branches of medical treatment are dealt with concisely and lucidly by recognised masters, whose names alone afford a guarantee of efficient handling. On exophthalmic goitre Prof. F. R. Fraser writes a model of what an article on medical treatment should be. We see the mark of the expert in the articles on eye diseases by Sir William Lister, on genito-urinary diseases by Mr. Hugh Lett, and on cardiovascular diseases by Dr. John Parkinson. Dr. J. D. Rolleston writes comprehensively on infectious diseases, Dr. P. H. Manson-Bahr on tropical diseases, and Mr. R. Milne on orthopædics. Mr. James Sherren's articles have been mainly revised by Mr. A. J. Walton, though Mr. Hugh Cairns has become responsible for that on the surgical affections of nerves. Dr. Sequeira's articles have been revised by Dr. J. M. H. MacLeod, and those of Dr. H. Russell Andrews by Mr. Victor Lack.

Among the subjects now included for the first time are anæsthesia for children, diabetes in childhood, erythræmia, glandular fever, hyperparathyroidism, pink disease, serum sickness, and treatment by protein shock and blood letting. Modern views on treatment have been admirably set out in many of the new sections, notably those on Addison's disease and gout. One of the most important and comprehensive articles in the volume is the account of radium therapy by Mr. Stanford Cade.

Where two authors have written under one heading the result is wasteful of space. Moreover, it is confusing to find one such author stating that in asthma injections of peptone are of doubtful value, whereas on the next page his coadjutor is evidently convinced of the opposite. Some of the subject matter has not been brought up to date. Nothing is more striking in modern therapeutics than the effect of a daily dose of Blaud's pill grs. 90 upon the microcytic achlorhydric anæmia of middle life; it is a little disappointing then, on being referred from secondary anæmia to chlorosis in this book, to find quite inadequate doses of iron recommended—for example, ferri sulphatis grs. 4 twice daily.

This edition has become bulky, and if the book were split into two volumes certain articles could be expanded with advantage. It is unfortunate that subjects like acromegaly and acholuric jaundice are given so little space—eight lines between them—whereas hyperthyroidism is given three pages. A good deal that is useful in therapeutics could be said about these two diseases, even in the space of half a page. But not only does the book cover the whole range of medical, surgical, and gynæcological practice from the point of view of therapeutics, the alphabetical arrangement of the subjects and the detailed accounts of treatment make it most suitable for ready reference by the practitioner. The system of cross references is excellent.

An Introduction to Gynecology.

By C. JEFF MILLER, M.D., Professor of Gynecology, Tulane University School of Medicine. London: Henry Kimpton. 1931. Pp. 327. 21s.

IN this elementary book, which is based on the author's course of gynæcological lectures to junior students, the teaching is orthodox and exceptionally clear. It has the disadvantage, however, that treatment is almost entirely excluded. Admittedly most text-books used in this country devote far too many pages to operative details which, although they furnish valuable anatomical exercises, can only be learnt properly at the operating table, and moreover are of little importance to those who do not operate. But pathology and treatment are too intimately connected for the one to be separated from the other, and the student will find his work more interesting from the outset if he is told something of the different methods by which morbid processes are attacked. An attempt has been made to explain the modern views on the function of the endocrine glands in the sexual physiology of the female, but the task, at the moment, is an ungrateful one because any account seems to be out of date as soon as it is written.

It is to be regretted that the Abderhalden reaction for pregnancy is not now ignored in text-books. This work of Abderhalden has never been confirmed and the test has never been used. Hardly any gynæcological work fails to mention this test, and hardly any gynæcologist has ever been known to use it. Surely it is time that it sank into the obscurity which it deserves, especially since the Aschheim-Zondek test is proving really useful.

The Essentials of Biology.

By JAMES JOHNSTONE, D.Sc. London: Edward Arnold and Co. 1932. Pp. 328. 16*s.*

Prof. Johnstone has given us a valuable book, whose title is over-modest if it suggests to the intending reader, by the word essential, that he will be offered only the skeleton of the science. The book presents a well-balanced account of the theories, their proofs and deductions, which make up our knowledge of animal biology, and although details in illustration are largely omitted, we have left a survey of the main results of the most recent work in biological fields, accompanying an epitome of recognised principles. Such a survey is particularly opportune, because biology has shared remarkably in the general development of scientific knowledge during the past fifty years, chiefly by the incorporation into its study of lessons derived from the equally progressive activities of histology, embryology, biometrics, and biochemistry. To this last Prof. Johnstone looks most hopefully as the source of new knowledge, at which no student of modern pathology will be surprised.

The book is divided into two parts, of which the first treats of the individual and the second of the race. In Part I. the organism is considered as a natural thing, the principles of structure, function, and behaviour are dealt with, and a notable feature in these chapters is the care with which all terms are employed, and the accuracy with which the definition of those terms is provided. As an instance a subsection on artefacts may be given. This word is often employed loosely, when it obscures the writer's meaning, leaving the student in doubt why these lifeless things belong to a different category than others which should be termed inanimate. In a section on types of organic structure we have, with the assistance of some neat diagrams, a synopsis of great clearness. No student could pass an examination on the subject by reading these notes, but if he were to use them as a synopsis to be supplemented by the study of one of the usual manuals he would find himself much aided. Indeed, this is typical of the book.

In the second part of the book two chapters, each of considerable length, will be thoroughly informing to many readers—that on reproduction and growth, and that on heredity. Defining heredity as "the progeny of an animal belonging to the same category of organisms as do its parents"—a definition which is admittedly incomplete—the thesis is amplified into a lucid essay on hybridity, Mendelian theories, and the transmission of characters, and is followed by a discussion of the hypotheses of transformism, such as natural selection, Lamarckism, and neo-Lamarckism. The book ends with a highly technical summary of the evolutionary career, and the suggestion that no results of modern biology will enable us to predict transformist processes. The future of the evolutionary career cannot be predicted, for evolution is essentially the appearance of novelties in a process. This is a really good book.

Regulation of Size as Illustrated in Unicellular Organisms.

By E. F. ADOLPH, Ph.D. London: Baillière, Tindall and Cox. 1931. Pp. 233. With 66 figures. 20*s.*

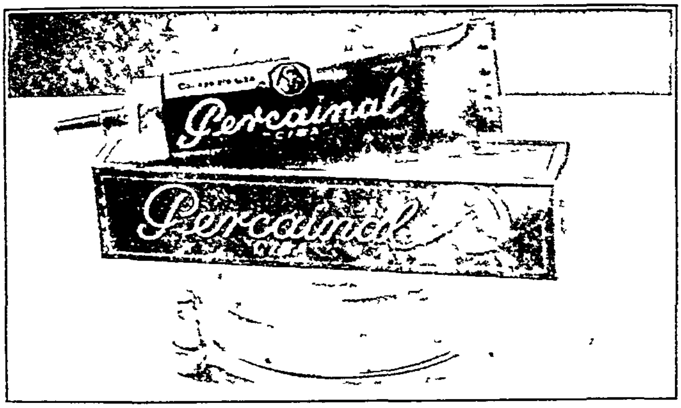
EVERY species of animal has a size which is proper to it, and a limit to the variation in size which is compatible with its existence: *Homo sapiens* cannot be as small as a rabbit or as large as a whale. Similarly in each group of animals there is an upper and lower limit: among terrestrial mammals the elephant and the pigmy shrew. What determines these sizes is one of the major unsolved problems of biology, and in this book Dr. Adolph has brought together the available facts and experiments in relation to the simplest forms—the influence of food, genetic constitution, and so on. The treatment is highly technical and the book will be of great service to students; there is a lengthy bibliography.

Female Sex Hormonology:

A Review. By WILLIAM P. GRAVES, A.B., M.D., F.A.C.S., *Professor of Gynæcology at* Harvard Medical School; Surgeon-in-Chief to the Free Hospital for Women and to the Parkway Hospital, Brookline. London: W. B. Saunders Co. 1931. 17*s.* 6*d.*

THIS is an interesting review of the recent developments in our knowledge of the internal secretions of the female sex glands, by a well-known American authority on practical gynæcology. The use of the word "hormonology" may give a wrong impression of the subject matter to English readers; the book is not a profound work but a simple readable account of the stages in the discoveries made by the various workers in this branch. The first few pages deal with the early history of the subject, and are followed by a brief description of the sexual cycle in animals, the discovery of ovulation, and the long and intensive search for the hormones of the ovary. The important part played by the hypophysis is next discussed, and five pages are devoted to the Aschheim-Zondek reaction for pregnancy and its clinical applications. Three chapters are devoted to new theories concerning menstruation, parturition, and lactation respectively, and a final chapter discusses organotherapy. The author confesses that at present very little is known about therapy, but claims that experimental findings are so promising that developments of the utmost importance may be expected in the future.

It is a pleasure to read a book by a clinician which gives an accurate picture of laboratory technique without over-burdening the reader with detail. Dr. Graves has evidently taken much trouble in selecting and verifying references, and the reader will find it easy to follow up the subject in any direction.



PERCAINAL
OINTMENT
"CIBA"

Analgesic, Antipruritic, Antiphlogistic & Astringent

For the treatment of all painful conditions of the skin and mucous membranes.

Eczema, macerations of the skin, bed sores, herpes zoster, chaps, cracked nipples, ulcera cruris, ulcers due to X-rays, intertrigo, pruritus ani et vulvæ, anal fissures, hæmorrhoids, burns, etc.

Collapsible tubes containing 40 grm.

THE CLAYTON ANILINE COMPANY LTD.
Pharmaceutical Department
40 Southwark Street, LONDON, S.E.1
Telephones: Hop 4474 (3 lines) + Telegrams: Cibadyes Boroh London

KOLA ASTIER

(GRANULATE)

THE STANDARD RECUPERATIVE

ASTIER'S KOLA
The best restorative after all exhausting diseases, especially after Influenza. Shortens and hastens convalescence.

ASTIER'S KOLA
The best pick-me-up in all run-down conditions. Not habit forming.

ASTIER'S KOLA
Activates the Nervous System, brings back Mental equilibrium, especially valuable in cases due to overstrain, mental or physical.

ARHĒOL

$C^{15} H^{24} O$

THE ACTIVE PRINCIPLE OF SANDALWOOD OIL

Gives better results than the best of the Balsamics

BLENNORRHAGIA CYSTITIS

ARHĒOL Certain in action. Definite in composition.

ARHĒOL Causes no digestive or renal complications.

LABORATOIRES P. ASTIER, 41-47, rue du Docteur Blanche, PARIS (XVI^e)

50% lighter— the new Plaster of Paris Bandage

50% lighter, cleaner, easier to apply and handle. Only half the thickness usually applied with any other Plaster of Paris Bandage is required. Cellona moistens in only 5 seconds. Setting can be regulated from 5 minutes upwards according to the amount of moisture retained in the bandage. Ready for use, and suitable for all supporting casts and splints.

Other Products:

ELASTOPLAST BANDAGES for all compression and support.

ELASTOPLAST DRESSINGS for all cuts, wounds, incisions, boils, etc.

SEMIPLAST elastic plaster. Only the first turn of plaster comes in contact with the skin.

VISCOPASTE — Improved Unna's Paste Type. Zinc and gelatine bandage.

100% BRITISH

Cellona PATENTED REGd. NAME

Order through your usual supplier or send for details to the manufacturers:

THE HOSPITAL ALMONER.

STATE and private enterprise in social service are linked by the work of the hospital almoner. n the annual report of the Institute of Hospital Almoners which has just been issued it is related hat there are now 76 hospitals in this country n which an almoner, trained by the Institute, s at work, and that there are 150 students in raining at various British universities. The modern almoner, unlike her mediæval prototype, s not merely a dispenser of charitable funds on behalf of another, an "amner to the poore that helpless cry." The nature of the work may vary according to the requirements of the hospital committee which appoints her, but the possible cope of duties is thus set out in the report. To acquire a knowledge of the patients' home conditions for the use of the hospital staff. To coöperate with other agencies in the provision of any requisite ordered, and generally to assist he patients in every way which will enable them to carry out thoroughly the prescribed treatment; and this may include not only convalescent treatment and the provision of instruments, but more extensive plans. To organise the after-care of patients on discharge. To maintain an adequate knowledge of the powers of State and municipal authorities, and to act in close coöperation with them in any matters which have a bearing upon the health and social conditions of the patients. If required, to discuss with patients and to collect their contributions towards the cost of their treatment. To check abuse of the hospital by patients who are (*a*) in a position to pay for private treatment; (*b*) insured under the National Health Insurance Act, entitled to the services of a panel practitioner, and not requiring special hospital treatment; (*c*) unable to benefit by any assistance other than that obtainable through public authorities. To administer Samaritan and other funds for the relief of patients, if called upon to do so. A glance at these duties will satisfy the most thorough-going advocate of social service.

Although inability to pay for the services rendered is not an essential part of the definition of social service, in practice such services are only intended for those who cannot afford them. At the same time the service is not necessarily a charity. In some form or other the patient has often contributed towards his treatment, and he is being asked to do so more and more every year either by some scheme of voluntary assessment, weekly contribution, or hospital savings scheme. He considers, too, that he has been obliged to contribute to his own treatment by indirect means, such as national health insurance payments, local rates and taxes, and he is quick to resent the suggestion that the hospital is a charity. In his mind it is a charity no longer any more than is the non-provided school to which he may send his children. Possibly it is this idea which is at the back of the public's mind in its lamentable failure to pay the hospital for the motor accidents, the treatment of which forms so large a part of the work of casualty departments. It is characteristic of the individualist outlook of the voluntary hospitals that no hard-and-fast rule has ever been laid down as to ability to pay. There is no instruction except that every case is a law unto itself, and it is left to the almoner to decide on its merits. This has never been an easy task for the almoner, and of recent years it has increased in complexity. The special departments which have developed with rapid strides during the last few years add much to the cost of treatment. A complete bismuth meal, biochemical investigations such as blood-sugar curves, artificial pneumothorax refills, and large chest radiograms are only a few examples of the manner in which the patient's treatment in special departments has increased the cost of administration; and these expensive items have to be paid for out of somebody's pocket, whether the hospital be State or voluntary. A patient who can perhaps just afford a doctor's fee cannot afford these extra charges and must seek the help of the hospital. These are problems placed upon the almoner, of which the public who contribute by rates or voluntary subscription know little or nothing. In the case of the voluntary hospitals the social service department is finding itself more and more in the position of a connecting link. There are many organisations—State, quasi-State, and voluntary—to which the patient may be and sometimes must be referred for help. As a rule he knows nothing of these posssibilities, and the almoner must direct and advise.

Few people realise how much raw material for research exists in the social service department. The investigations into the fate of children in tuberculous households, and into rheumatism in childhood, are concrete instances which may be cited, and there are numerous others. There are types of cases also which need a careful follow-up inquiry in order to establish certain facts of remote results. Such a task frequently falls to the lot of the department which possesses the necessary machinery for the work. And, lastly, there is looming in the not far distant future a reorganisation of the hospital out-patient department in which machinery must be devised to eliminate the long period of waiting which patients still so often have to undergo. Presumably some system of appointment as in private practice will be evolved. Here again to the social service department may well be entrusted the task of working the scheme. One such is already in operation at the Peto-place Clinic, where during the past year every attendance for treatment has involved a specific appointment, and in the majority of cases the patients arrived at the stated times and were not kept waiting.

Evening appointments give patients in the early stages of rheumatic disease the opportunity of treatment after working hours. Both these innovations enhance the hospital's opportunities for service. The objection is sometimes raised that a hospital cannot afford a social service department. It would be nearer the mark to say that a hospital nowadays cannot afford to be without one. It must be evident to all those who work in them that a large amount of the sickness which hospitals try to cure is preventable ill-health. In the future the work of the social service department will increasingly be that of investigation of the economic conditions of the patient, in the same way as the work of the pathological department is an inquiry into the causes of disease. In other words, the social service department is in reality a unit complementary to the medical, surgical, and pathological units of the hospital.

SIMPLE PNEUMOTHORAX.

A VALUABLE addition to our knowledge of the lung has been made by the publication of HANS KJAERGAARD's monograph[1] on Spontaneous Pneumothorax in the Apparently Healthy. The condition has been described in France as *Le pneumothorax des conscripts*, an expressive phrase which indicates the incidence of the malady among the young and apparently healthy. All observers are agreed that simple spontaneous pneumothorax represents a separate clinical entity, having no relation with the secondary pneumothorax that may result from the caseation of advanced tuberculosis, the breaking down of malignant tumours, or ulceration due to purulent disease of the lung. It falls like a bolt from the blue, as a rule gives rise to no complications, and heals spontaneously in the course of a few weeks. The cause of the accident has been a subject of discussion since McDOWELL published the first description of a case in 1856. There are difficulties in accepting either of the two theories which have been propounded to explain the origin of an apparently spontaneous accident, the rupture of an emphysematous bulla, or the ulceration of a subpleural tubercle. Emphysema is far more common in the second half of life than it is in the first. Further, spontaneous pneumothorax is seldom a complication of the pulmonary diseases which are associated with emphysema in early life. It occurs in the apparently healthy. On the other hand, if lung rupture of the type under consideration were due to the ulceration of a tuberculous focus, we should expect at least a proportion of cases to be followed by tuberculous pleurisy or by pulmonary tuberculosis. It is noteworthy that simple spontaneous pneumothorax is not the precursor of either. The rupture is sometimes recurrent, but even when recurrence occurs the patient remains free from any signs of tuberculous disease.

As simple spontaneous pneumothorax is rarely fatal there have been few opportunities for pathological investigation of the condition of the lungs. Dr. KJAERGAARD describes the post-mortem appearances as noted by various observers at six autopsies. In each case the cause of the pneumothorax was found to be the rupture of a solitary vesicle at the apex of the lung, but such an explanation is not always forthcoming. In some cases no cause can be demonstrated despite careful pathological investigation. If the rupture of an air vesicle is accepted as the usual cause of spontaneous pneumothorax, an explanation both of the formation of the vesicle and of its subsequent bursting is called for. A Japanese investigator, J. HAYASHI, at an autopsy on a patient who had had spontaneous pneumothorax, discovered small vesicles at the lung apex, near the bases of which scar tissue was seen. Microscopic examination proved that deformed atrophic lung tissue formed a valve-like structure at the base of the vesicle, permitting air to enter but not to leave it. It is easy to understand how in these circumstances increasing intravesicular pressure might result in rupture. Dr. KJAERGAARD has demonstrated similar vesicles in the lungs of persons who had not suffered from lung rupture, in two instances the pulmonary scarring being due to an old tuberculous fibrosis. It is thus probable that *pneumothorax simplex*, to adopt the author's nomenclature, is due to the bursting of valve-vesicles of a kind similar to those described. It is also possible that some of these structures are due to the apical tuberculous scars that are so often found at autopsy unassociated with any evidence of active disease.

Spontaneous pneumothorax is probably a less rare condition than it is usually supposed to be. Symptoms are seldom severe, and the practitioner who does not bear in mind the possibility of such an explanation of sudden thoracic pain may be discredited if his patient should feel that "a stitch in the side" is an inadequate explanation of his symptoms, and seek advice from a radiologist. The condition when diagnosed is sometimes wrongly treated by prolonged sanatorium residence. Whatever the ætiology of the disease it is not the precursor of phthisis, and treatment which may be appropriate for a tuberculous pleurisy should not be recommended. The patient should be reassured as to his future, rest need not be continued for long after the lung has fully re-expanded, and after a short convalescent holiday a return to work should be permitted, provided that the lung has completely re-expanded. Such a programme, however, obviously does not apply to the rare cases in which recurrent rupture, the effusion of blood into the pleura, the persistence of pulmonary collapse, or other complications demand special treatment and prolonged care.

A QUARTERLY HEALTH BULLETIN.

THE Health Organisation of the League of Nations which came into existence ten years ago publishes records of international conferences and other occasional papers, but has hitherto limited its regular output to a weekly fascicle and a monthly report on the world incidence of idemic and other diseases. In the monthly port, it is true, space is reserved for a more tended account of some disease of topical terest, but since the report circulates only mong medical administrations and health officers s scope as a medium for expressing the more eneral work of the health side of the League is stricted. Those who wish to follow this work ave been obliged to pick out for themselves e main features of health interest in the general ass of League literature—a task of no mean rder. To make this material more accessible nd consequently more widely known it has been ecided to embody it in a new periodical,[1] entitled e *Quarterly Bulletin of the Health Organisation*, ublished in two editions, French and English, he first number of which has just appeared. hose whose appetite is whetted by reading he articles which it contains can readily obtain he full literature on which they are based. The act that some of the articles are the first of a eries on the same subject should be noted. In ubsequent issues the contributions will no doubt ome to have a natural and well-understood order ; eanwhile the present issue serves to illustrate ow the Health Organisation touches many and aried branches of medicine.

---

[1] Acta Med. Scand., vol. xliii., suppl.

The first article in the *Bulletin* presents the esolutions of the London conference of June, 931, on the value and use of immunising agents n the prevention of diphtheria, at which the nglish representatives were Sir Henry Dale, r. E. H. R. Harries, Dr. P. Hartley, and Dr. . A. O'Brien. These important resolutions, of hich we print the text on p. 1165 of our present ssue, commend themselves in the main to opinion n this country where there is general agreement rom experience amongst nurses in isolation ospitals and children in residential schools—otably those at Greenwich, Mitcham, and orwood—that efficient immunisation abolishes iphtheria. Resolution 2 puts in its right place the occurrence of reactions after injection of prophylactic, for in the immunisation of children little trouble is encountered whatever prophylactic be used. We cannot trace any significant number of reports of trouble in England from the prophylactics employed, and Dr. E. H. T. Nash showed as far back as 1924 that a group of children could be injected with formol-toxoid without suffering inconvenience. As Nash also found, it is amongst adolescents and adults, still unimmunised in this imperfect world, that undesirable reactions are likely to occur, particularly when formol-toxoid is used. Formol-toxoid (anatoxin) is recommended ; it is not clear how far the prophylactics most favoured in England, toxoid with antitoxin — either as mixture or floccules—are here included. The suggestion in Resolution 6 that when subcutaneous injection is not possible prophylactic may be applied to the nasal mucous membrane will probably surprise English workers. The conference resolved that it is unnecessary to carry out the Schick test before immunisation. There certainly are conditions, particularly in work on the large scale and where the natural positive rate is high, in which some administrators might feel free to discard the test, but amongst urban children, where more than half may be immune before presenting themselves for immunisation, and after immunisation, most of our own health officers prefer to use the test. The suggestion that immunisation should be postponed until after the child is twelve months old may be wise as a general rule, though since diphtheria is often met with in the second six months of life, some feel that immunisation should be commenced when children are six months old. The resolutions as a whole received the official approval of the Health Committee as long ago as October, 1931 ; they merit close attention from public health and school medical officers in the country and should be known to every practitioner.

The *Bulletin* contains a compendious report by Sir George Newman on medical education in England, the first of a series to be devoted to the study of problems raised by medical training in European and overseas countries—a study, we are told, arising out of a request made to the League of Nations by the Chinese National Government. The report consists of an introduction to the general conception of medical education, its function and purpose ; an account of the hierarchy of medical practice in England ; and a critical review of the existing system of medical education. A report by Prof. R. Burri, director of the Institute for Milk Industry at Berne, on the milk-supply in towns in the United States, is the outcome of a desire for further knowledge on the modern practice in milk control expressed at the International Conference on Rural Hygiene held at Geneva in June, 1931. Lieut.-Colonel A. G. McKendrick reviews the results of anti-rabies treatment as practised at the various Pasteur Institutes of the world. This is the second analysis of its kind carried out on behalf of the League in pursuance of a decision taken by the International Rabies Conference which met at Paris in 1927. Of 69,707 persons treated for whom records were available (of whom no less than 53·5 per cent. were Europeans) 333 died of rabies, a mortality of 0·48 per cent. Of the biting animals 87 per cent. were dogs. The figures submitted indicate a probable advantage in favour of the modified dilution methods of Hogyes and Hogyes-Phillips. In an article on tropical pneumonia, Dr. R. Gautier, a member of the Health Organisation, deals fully with the ætiology, prevention and treatment of this malady, whose case-mortality may be as high as 58 per cent. He advocates a plan of campaign to study the peculiar susceptibility of natives to the pneumococcus and of the types of pneumococci existing in the various tropical countries so as to allow in future for the use of homologous vaccination and serotherapy. Finally, there is a report by Dr. Rajchman, medical director of the Health Organisation, on the work undertaken by the League to protect the population endangered by the recent floods in China.

ANNOTATIONS

THE RESURRECTION MEN.

A PICTURE of the more famous crimes associated with the activities of the resurrection men, and entitled "The Inhumanists,"[1] suggests the question why those activities have become of topical interest. Did Dr. McBride, in the terrible little play which we recently reviewed in these columns and which was afterwards played with success in a London theatre, popularise body-snatching as a theme for a drama, or did he respond to the feeling that at the present moment the public were curious concerning a subject which 100 years ago was of terrible import? Mr. Turner sketches correctly the circumstances both of the law and of medical education which led to dead bodies becoming an article of merchandise to be dealt in by those in charge of anatomy schools on one side and the disreputable order of Jerry Crunchers on the other. He goes on to narrate with horrid detail the methods taken by resurrection men and the counter-measures of the forces of the law, finally relating a series of sensational crimes. We have here something of the skill of Poe in painting lurid pictures, and the excerpts from the diary of Joseph Naples, in possession of the Royal College of Surgeons of England, rival anything Poe ever wrote in their cold horror. In this diary a leading resurrectionist records his activities as body-snatcher and gravedigger, setting down his crimes as the items of a day's work. In one chapter Mr. Turner draws an analogy between the methods of the modern American gangster and those of the London resurrectionist a hundred years ago, which shows how seldom a precedent cannot be found for the law-breaker. "Like modern American racketeers," he writes, "rival gangs of resurrectionists had allotted territories both for producing and marketing, but these arrangements fell to pieces as the supply failed to keep pace with the demand, and ruthless inter-gang warfare broke out. The paramount corpse king would fix famine prices and ask as much as 20 guineas for a single body. A rival gangster would offer supplies at a lower price and obtain the contract, as it were, but as soon as the corpse king knew of it the price-cutter would be shadowed day and night until an opportunity occurred to betray him to the police in the act of exhumation, and he would be put out of the way for six months or so." An impulse to write "The Inhumanists" seems to have been the author's feeling that Edinburgh is wrongly accused of having been the original centre of the body-snatching trade—a reputation acquired by the tremendous excitement over the Burke and Hare murders—whereas, says Mr. Turner, London was the real centre, one famous London surgeon being the mainspring of the trade. To-day the enlightened coöperation of public authorities, kept alive by the official inspectorship of anatomy, ensures the supply of subjects to medical schools.

A NEW FACTOR IN THE CAUSATION OF OSTEOMALACIA.

LAST year in our columns Dr. Dagmar Wilson gave a very interesting account of osteomalacia in the Kangra Valley in India. Osteomalacia in India as a whole attacks women, and amongst women only those whom the custom of purdah confines to the house, but in the Kangra Valley there are two outstanding peculiarities: men as well as women, and field workers as well as people keeping to the house, are affected. Clearly some new factor must come into play. The most likely contributory factor would be a salt deficiency, a deficiency of calcium or of phosphate in the diet, of so severe a degree as to leave the body in negative calcium balance, even though exposure to the sun was quite considerable. In cattle such a state of affairs, due to a phosphate deficiency in the pastures in certain parts of the world, is well known. Since last summer Dr. Wilson has put this theory to the test, and relates in our present issue that in the case of persons not starved of sunlight a daily dose of tricalcium phosphate caused rapid alleviation of the painful symptoms, but that in those deprived also of sunlight the addition of the salt caused little benefit; in the latter case the deficiency would be a dual one, of vitamin D and calcium or phosphate, and correction of the salt deficiency alone would not effect a cure. The season at which the cures took place is not mentioned, but presumably there is no likelihood that they could be attributed to change of season, as was, for instance, the case in untreated cases of hunger osteomalacia in Vienna in the post-war years. Dr. Wilson is indefatigable in her efforts to help these suffering people as well as in the pursuit of knowledge, and her work has the additional merit of being truly practical, in that she constantly endeavours to find means of making up these dietary deficiencies which shall be so cheap as to be easily accessible to the poorest in India. Thus she has also made trial of sun-irradiated yeast as a source of vitamin D, and finds that it is efficacious in those cases of osteomalacia where there is a deficiency of that vitamin, such cases being, as has been pointed out, the vast majority of those which occur in India.

NORMAL GASTRIC ACIDITY.

EXTREME variations in gastric acidity are known to occur in normal individuals and to be compatible with perfect health. No normal constant value is therefore available and this is a serious disadvantage in interpreting the results of test-meal analyses. Hyper- and hypo-chlorhydria are purely relative terms, compared with an "average" degree of acidity as judged from a number of analyses; but for any individual "average" acidity is not necessarily the normal. Moreover, varying types of test-meal curves may be obtained in the same individual under different circumstances. Factors influencing the curve include the type of meal and the age of the patient. Attention has lately been focused upon the changes that may normally occur with advancing years. Some workers at the Mayo Clinic have examined[1] the results of gastric analyses in 3746 persons in whom they were satisfied that no disease affecting gastric secretion was present. The test-meal employed was a mixture of "eight arrowroot cookies and 400 c.cm. of water," and in general the one hour sample was used for analysis; in some cases histamine was used in addition as the stimulus. The conclusions drawn are as follows: Free gastric acidity appears to increase rapidly from childhood up to the age of 20 years; in men the average free acidity, at one hour, lies within 45 and 50 units

---

[1] The Inhumanists. By Cecil Howard Turner. London: Alexander Ouseley, Ltd. 1932. Pp. 286. 8*s.* 6*d.*

[1] Vanzant, F. R., Alvarez, W. C., Eusterman, G. B., Dunn, H. L., and Berkson, J.: Arch. Int. Med., 1932, xlix., 345.

(c.cm. of N/10 sodium hydroxide required to neutralise 100 c.cm. of gastric juice) between this age and 40, after which it falls to a level of about 30 to 35 units. In women 30 to 35 appears to be the normal level throughout adult life. At the age of 60 some 28 women in every 100 fail to show any free acid on fractional analysis and 23 per cent. of men are similarly achlorhydric. Other workers have also noted this high percentage of achlorhydria in normal persons over 60 years of age, and it has been suggested that this is the result of a senile atrophy of the gastric mucosa. The authors of this investigation attribute it to a hereditary tendency rather than to a morbid process.

These studies of gastric acidity certainly provide useful data for future comparison, even if the hope of the authors that they will be now able to "detect with certainty small abnormalities in the secretory power of the stomach due to disease," is not realised. It is difficult to believe that small variations in gastric acidity would ever be of great practical significance. As our knowledge of gastric secretion increases it appears more and more probable that gastric acidity is at least in part dependent upon a general condition of the body. For example, the high acidity common in duodenal ulcer is more likely to be the predisposing factor to the formation of the ulcer then a reflex effect produced by the ulcer. It is significant that the highest acidity is normally found in men between the ages of 20 and 40, at which time the incidence of duodenal ulcer is highest. As we have already observed[2] it is possible that gastric acid secretion provides one means of maintaining the acid-base equilibrium of the body, and is thus subject to variations in the blood and tissues outside the stomach. The data here recorded may therefore be regarded as suggesting rather the soil upon which ulcer or carcinoma, for example, may develop, than as providing a set of standards for the comparison of the changes found in gastric disease. The narrow view that various types of test-meal curves are produced by local disease in the stomach and are diagnostic of such disease is giving way to a broader conception of a gastric "constitution" upon which disease tends to form.

THE POSITION OF MEDICAL RESEARCH.

The Journal of the Research Defence Society, entitled the *Fight Against Disease*, contains in its latest issue an analysis of the 1876 Act (Act 39 and 40 Vict. cap 77) under which research involving the use of living animals is permitted in this country. Medical progress has been impeded, and research workers have been harassed with malevolent accusations against them, by vigorous antagonists, but many, if not all, of the points upon which public opinion asks for information will be found in the wording of the Act, whose relevant passages are cited in the journal. Restrictions upon the performance of experiments on living animals are categorical, and so are the provisions under which in certain cases these restrictions may be modified. The issue of the licences, making the research work legal, is carefully controlled, and prompt legal proceedings can be taken against the author of any experiments in contravention of the Act. The public is gradually appreciating in greater measure on which side truth lies, and the recent action of the Anti-Vivisection Hospital makes it clear that the opponents of experimental research, some of them at any rate, realise that inhumanity may result from actions which are taken expressly in the cause of humanity. The authorities of this hospital are now prepared to empower the administration in their hospital of anti-tetanic serum in accordance with accepted medical knowledge, and the London County Council has withdrawn accordingly its embargo against the taking of accident cases to the institution by their ambulances. The journal announces that Sir Arthur Keith will give the next Stephen Paget memorial lecture at the annual general meeting of the Society on Wednesday, June 15th, in the lecture hall of the London School of Hygiene and Tropical Medicine.

CONTROL OF SCARLET FEVER IN INSTITUTIONS.

Until a few years ago the measures available for the control of an outbreak of scarlet fever in an institution or in a children's ward were limited to the removal of clinical cases to an isolation block or the fever hospital and the quarantining of those exposed to the disease. The occurrence of dropping cases at irregular intervals might prolong this period of quarantine indefinitely, and meanwhile the work of the institution or ward was badly hampered. Save by a few rare spirits, the hæmolytic streptococcus described by the Dicks has been accepted, upon evidence which is really overwhelming, as the causal organism of the disease. As M. L. Blatt and M. L. Dale[1] point out, the subsequent discovery by the same workers in 1924 of the production of a specific toxin and of its antitoxin have together permitted of a rational scientific programme for controlling the disease. Most of the measures now available are in routine use in many fever and children's hospitals in this country and have been described in our columns by R. A. O'Brien.[2] They were employed systematically and successfully by Blatt and Dale in the control of an outbreak in an infant and maternity hospital in Chicago at a period when scarlet fever was very prevalent in that city. The significance of periods as long as 19 and 14 days between the first four cases did not at first suggest anything unusual to them, but a fifth case occurred at a further long interval under conditions which suggested that adult carriers having access to any of the five floors of the institution were the means of transmission. Thereupon rigid preventive measures were instituted. All clinical cases had been already removed to a fever hospital. The adult patients and staff, amongst whom were discovered seven with positive cultures, were required to wear, except at meals which they took together, gauze masks until three platings upon blood agar could be shown to be negative for hæmolytic streptococci. Children with positive cultures were isolated in special wards on their respective floors. A Dick test was performed upon everyone in the hospital. Three children amongst those who had been in most recent contact with the last cases were found to be positive reactors. These were passively immunised with scarlet fever antitoxin and a week later active immunisation by means of multiple skin test doses of toxin was begun. All other positive reactors amongst patients and attendants, except three very young infants, were actively immunised. The last case of scarlet fever developed two days after these measures were taken; significantly, in a positive reactor who had not received antitoxin. The institution was not closed to admissions, but during the succeeding six weeks Dick tests were done and cultures obtained in the case of all new entrants, and if necessary immunisation was carried out. No further cases developed. Commenting on the procedures Blatt and Dale note that the Dick toxin used for active immunisation produced severe reactions in many older children and adults although, with one exception, active immunity was brought about in a month by five graded doses of toxin at five day intervals. Of the 176 children originally tested 43 (24 per cent.) were positive. It was possible to retest 56 of the original 176 infants six months later. The others had presumably left the hospital. Of 13 originally immunised Dick-positive reactors a four months old infant, negative one month after immunisation, had again become positive. Of 43 original Dick-negative infants five gave a positive test six months later. These "mutations in skin reactivity" in this small series of infants are doubtless to be explained in the same way as similar changes in the sign of the Schick test in infants. They are due in the one case to the inhibiting effect of maternally transmitted passive immunity upon the production of active immunity and in the other to the gradual waning of this passive immunity as the months pass.

THE CAUSES OF FILARIAL SYMPTOMS.

In a paper read at Manson House, before the Royal Society of Tropical Medicine and Hygiene on May 19th, Dr. F. W. O'Connor, of the Presbyterian Hospital, Columbia University, New York, dealt with the factors which underlie the disease syndrome in infection with *Wuchereria bancrofti*, as its valid name now is. Having pointed out how the original conception, that the symptoms of filariasis were due to the filaria, had tended to give place to one implicating bacteria as essential in causation, he marshalled evidence, much of it new, against this conclusion. He first pointed out the territorial correlation between the symptoms, the filaria, and the local insect vector, and the striking lack of correlation between chronic filariasis and bacteria; strengthening his argument with similar instances in other lymphatic diseases. He surveyed the bacteriological studies made in connexion with filariasis, and showed how often, even in acute filarial lymphangitis, cultures from blood and from local material have been sterile; and it is of course the many instances of failure by experienced bacteriologists to grow bacteria which are here of positive importance. The successful instances he attributed to secondary infections of the skin caused by the scratching induced by the intense irritation found in this condition so soon as acute symptoms cease, scratch marks being a striking feature of these cases. Next followed the inquiry as to whether the clinical and pathological features of filariasis were such as to establish the responsibility of the parasite for them. His reading of the histological evidence is that, provided there is lymphatic obstruction higher up, living worms produce a polypoid endothelial proliferation of the lymphatic vessel in which they live, which stops short of complete occlusion but nevertheless often suffices to kill the parasite; when, however, this dies complete occlusion may be expected. The share of the daily death and daily destruction of microfilariæ (for evidence in that direction accumulates) in the production of ill-effects needs further study. Regarding attacks of acute lymphangitis, the conclusion was reached that they are allergic, and correspond to a moment when death of worms liberates sufficient protein to overcome the resistance set up by previous sensitisation. For the reality of hyperfilariation—a matter which had been constantly in Sir Patrick Manson's mind, of its apparent commonness in young people in endemic areas, and of its ability to produce directly or indirectly the blockage which results in elephantiasis and other lymph stases, Dr. O'Connor gave striking evidence. The cumulative effect of the steps in his line of argument—that the filaria is the essential cause of the symptoms constituting the filarial syndrome—was impressive and met with acceptance.

Perhaps the most striking point which came out in the subsequent discussion was the difficulty of drawing safe general conclusions in the present state of knowledge. In Grenada, for instance, the ordinary insect host is present and can be infected, but the disease is absent. We are ignorant of what happens to the microfilaria in the cryptic hours between midday, the hour about which, as Dr. O'Connor's investigations indicate, parturition takes place when there is microfilarial periodicity, and midnight, the hour about which the numbers of these larvæ reach their height in the blood. The different aspect of the filarial syndrome in different geographical areas was mentioned, with the suggestion that the details of the lymphatic system had not perhaps precisely the same structure in different races of man. That the presence of elephantiasis was accompanied by hitherto unsuspected biochemical changes was shown by a cited instance in which skin reactions to the dirofilarial antigen of Hamilton Fairley (see p. 1167), markedly different from the normal, developed when it was injected into elephantoid skin. The further investigations which Dr. O'Connor is about to carry out in Porto Rico are being undertaken in the hope of advancing knowledge on these and kindred matters by an extension of the methods which in the hands of his technical staff have already given such fruitful results.

VITAMINS AND RADIATION.

Vitamin research has for many years engaged the attention of physiologists and biochemists and has of late been a field of work chosen by pure organic chemists. The progress recently made towards the identification and preparation of these once mysterious substances has been astonishingly rapid, so much so that a stage has already been reached when profitable attempts may be made to determine their actual molecular structure. Physical chemists are now taking up this problem, and F. P. Bowden and C. P. Snow,[1] of the Laboratory of Physical Chemistry, Cambridge, have lately reported a series of experiments which promise to shed light on the constitution and possible methods of production of the vitamins. They employ photochemical and spectroscopical methods to follow the changes which take place in the structure and properties of certain of the vitamins and pro-vitamins as the result of exposure to radiations of strictly defined wave-length, the essence of their technique being to employ monochromatic light as the source of radiation instead of using light filters. Their results already suggest that they may have accomplished the actual conversion in vitro of the pro-vitamin carotene to vitamin A. On spectrographic analysis carotene shows characteristic absorption bands, one of these being situated at 2700 A. A solution of carotene was exposed to radiation of about this same wave-length—namely, 2650 A, selected from the spectrum of mercury.

---

[1] Nature, May 14th, p. 720.

er a few hours of such irradiation a new absorp- band appeared in the spectrum of the solution, ated at 3280 A, and an absorption band in this ation is fairly generally recognised as character- c of vitamin A. The obvious presumption is that otene has been converted to vitamin A by the diation and further work is now in progress to ermine by other methods, including biological periments, whether this conversion can in fact proved.

The new work brings to mind at once the ll-known method of producing vitamin D by diation of its parent substance ergosterol. Just it has long been known that exposure to radiations short wave-length can destroy vitamin D as well bring about its synthesis, so it now appears that amin A can be destroyed by exposing it to radiation suitable wave-length. Similar results were obtained h vitamin B_1; it was apparently possible to stroy the activity of Jansen and Donath's "crys- line vitamin B_1" by subjecting it to radiation 2537 A. It seems possible that the monochromatic ht technique may lead to important advances in owledge of the constitution of the vitamins.

ANOREXIA NERVOSA.

IN the tenth annual report of the Cassel Hospital : Functional Nervous Disorders the medical director ves a summary of the 13 cases of anorexia nervosa at have so far been treated at Swaylands. He fers that the prognosis is good, that a comparatively nple treatment alone is necessary, and that the ndition is a psychological one with no primary ysical problems. He lays stress on the clear defini- on of the syndrome, and corroborates the description it given by the Medical Society of Individual sychology.[1] It has, he says, seven characteristics, hich were present in all his cases. The three sitive symptoms are anorexia, loss of weight ometimes carried to the point of emaciation), and nenorrhœa; three other characteristics are that e patient is female, unmarried, and of an age etween puberty and about 24; and a constant egative symptom is that, despite her "deathly ppearance," she stoutly maintains that she is never red. Dr. T. A. Ross's insistence on the monosexual cidence is interesting. At a discussion held by he Medical Society of Individual Psychology in the pring of last year,[2] Dr. W. Langdon Brown described ur male cases, and Dr. G. Gordon described mild ases among men over 30 in suicidal wards; but r. Ross points out that young men sent to hospital ith anorexia and emaciation without physical lesion re, as a rule, the subjects of grave mental disease ith delusions, and are therefore in a different ategory. Dr. Gordon was obviously referring to rankly psychotic cases, and Dr. R. D. Gillespie[3] ays that he has never seen the symptoms "in pure ulture" in a man. Dr. Ross qualifies the restriction o unmarried girls by admitting that he has met ocially a married woman obviously suffering from he disorder, but that she was childless; Dr. Langdon Brown related adult cases in married women, but these seem to be rare. Dr. F. G. Crookshank, in the discussion mentioned, distinguished the reaction in young persons as a move towards independence, and in adults over 30 as constructive suicide. It is the experience of the Cassel Hospital that patients are not brought under care until they have been ill for many months, and it has become a point of honour to continue the illness. Deep psychological examination has not proved to be necessary, but on superficial examination most of the patients have shown a dread of becoming fat, and a few have been afraid of becoming conspicuous through development of the breasts. Although dominance of the mother was found to be important, in accordance with the experience of speakers at the discussion, Dr. Ross says that in some cases the parents were meek enough; that anything might upset the equanimity of these patients and the condition could not be correlated with anything specific. One patient appeared to have been jealous of a brilliant brother, and to have desired to attract attention. The case-histories have failed to explain the amenorrhœa; the stoppage does not seem to be the result of the emaciation and the menses often do not return until some months after recovery. Eleven out of the 13 patients did well, and the details given in the report are of great interest. Parents nearly always report improvement in disposition as well as in physical state. Treatment is based on the Weir-Mitchell method of rest in bed and increasing diet, absolute isolation from family and friends, and massage. A nurse should watch for the first few weeks to see that food is swallowed, but patients coöperate heartily in the treatment once they realise that the doctor is in earnest. No reliance is placed on elaborate systems of diet such as the one recommended by Dr. R. S. Allison and Dr. R. Picton Davies.[4] The two patients who did not become well cannot be called failures; one gained 10 lb. in six weeks and was then obliged to go abroad and has not been heard of since; the other has been at work since discharge but is thin and a food faddist.

PENTOSE NUCLEOTIDE IN LEUCOPENIA.

AT a meeting of the American Association of Physicians, held at Atlantic City on May 4th, further successful results in the treatment of certain intractable forms of anæmia were reported by Dr. Henry Jackson, Jr., and his collaborators at Harvard. They had previously recorded [5] the treatment of 20 cases of agranulocytic angina and other forms of malignant neutropenia with Nucleotide K96,[6] and since that time an additional 38 cases have been treated by them by the same method, no other specific treatment being used. Of these 58 patients, 43 suffered from typical agranulocytic angina, 13 from extreme leucopenia following sepsis, and 2 from very severe benzol poisoning. In all 41 recovered completely, including 28 in the first group, 11 in the second, and both cases of benzol poisoning. The prognosis did not seem to be affected even by a white cell count below 1000, complete absence of polymorphonuclear neutrophils, or extreme hyperpyrexia. The method of treatment is as follows: 10 c.cm. of the preparation is injected intramuscularly twice a day until the white cell count has definitely risen. An injection of 10 c.cm. is then given intramuscularly once a day until the count has been essentially normal on at least three consecutive days. Thereafter the patient is watched for a possible relapse. In certain resistant cases a rather larger dose led to a distinct increase in white blood-cells, when the usual dose had not been effective. As a rule few if any untoward reactions are observed;

but occasionally nausea, precordial distress, and dyspnœa occur, and much more rarely there may be a rise of temperature. Clinical and hæmatological improvement are said to occur consistently about five days after treatment is instituted, irrespective of the previous duration of the illness. The preparation appears to be of no value in leukæmia, aleukæmic leukæmia, or aplastic anæmia. This is important in so far as the differential diagnosis between agranulocytic angina and aleukæmic leukæmia is not easy without examination of the bone-marrow. Toxic symptoms following arsenobenzol therapy are now happily rare, but as we pointed out two years ago[1] agranulocytosis is probably far commoner than the number of cases recorded would suggest. It has hitherto proved fatal in a large proportion of the cases diagnosed, and the results recorded by the Harvard workers with nucleotide are therefore most encouraging.

AGE OF DENTISTS.

In the course of his twenty-second address from the chair at the Dental Board of the United Kingdom, Sir Francis Acland gave some interesting figures which had been got out in his office as to the ages of dentists registered under the Act of 1921. Their average age is 47¼ and the average expectation of life of persons of this age is 22 years. "I am afraid," said Sir Francis, "to dogmatise about averages, for I do not visualise them in a concrete form like the boy who said they were 'things hens laid eggs on,' and therefore I cannot say whether this means that this is the average expectation of life of persons of this *average* age, nor whether the figures mean that in 22 years half the total number, which is 6748, will probably still be alive." It may be of interest, he added, to give the numbers in different age-groups. There are 5 between 80 and 84 years, 103 between 70 and 80, 687 between 60 and 70, 1683 between 50 and 60, 2676 between 40 and 50, and 1594 between 32 and 40 years.

THE CAROTID BODY.

In an annotation last week we quoted the statement that Czermak was the first to note that compression of the vasculo-nervous bundle in the neck produces slowing of the heart beat. But, as Sir Thomas Lewis points out in a lecture on vasovagal syncope and the carotid sinus mechanism,[2] this observation was really made by Caleb H. Parry, who described it in his Inquiry into the Symptoms and Causes of the Syncope Anginosa, commonly called Angina Pectoris (1799). In his lecture Lewis brings forward the interesting hypothesis that the central and efferent parts of the carotid sinus reflex mechanism are disturbed in the syndrome of common fainting attacks —or, as he calls them, vasovagal syncope—in which strong vagal effects are combined with depressor vasomotor effects. In support of this he suggests that the alimentary symptoms associated with vasovagal syncope may be the result of alteration in the alimentary tract movements previously noted by Danielopolu to take place when pressure was made on the carotid sinus—namely, an initial inhibition followed by increased activity of the stomach. The form of syncope to which he refers should be distinguished from the "vasovagal" attacks described by Gowers in which consciousness is seldom or never lost. Dr. J. A. Ryle,[3] however, defends the latter use of the term, since his experience suggests that both vagal and vasomotor phenomena form part of Gowers's syndrome.

ÆTIOLOGY OF ALOPECIA AREATA.

Of all dermatological problems none is more provocative than alopecia areata. The current theories of its causation are generally familiar. There is focal sepsis in teeth, tonsils, and alimentary tract; Jacquet's dental reflex hypothesis; the older theory of exogenous infection; trophic nervous disturbance; and finally an endocrine vago-sympathetic syndrome. But none of these suffices to explain the symptoms in a scientific sense. Armas Cederberg,[1] of Helsingfors, holds that of all concurrent or associated manifestations oral sepsis appears to be the commonest, and this is perhaps true. But the association does not imply that the sepsis is to blame for the alopecia, and Sabouraud in his latest monograph on the subject[2] cites more than one unhappy case of total dental clearance without a particle of benefit to the hair loss. H. W. Barber, on the other hand, has seen recovery after tonsillectomy and the use of a streptococal vaccine, and it has certainly become the custom in English clinics to examine the mouth and throat in every case of alopecia areata and usually in vitiligo too. Cederberg, however, is not content with the streptococcal as the specific element in causation. According to his researches, oral and dental spirillæ are the true cause, and reach the lymph channels and the general circulation either through microscopic abrasions of the mucous membrane, or in symbiosis with other organisms. A further stage in the thesis asserts that spirillar infections are characterised by a characteristic affinity for the pigment and pigment-forming apparatus of the skin, whether manifested by hyperchromia or a deficiency in that respect, as in vitiligo. The most obvious example of such cause and effect is the case of syphilis, in which modified types of alopecia and vitiligo are both observed, while a spirillar (not spirochætal) balanoposthitis is not infrequently followed by more or less permanent local leucoderma and marked disturbances of the genital pigment distribution. For direct proof of the ætiological rôle of spirillæ in alopecia, their demonstration in situ is necessary, and Cederberg claims to have succeeded in several cases after prolonged search. He submits two microphotographs in support of his claim, taken from sections of a recent case of alopecia areata. Single organisms are observed, stained by the Levaditi process in the interstices between epithelial cells, and in the lymph channels both in the epidermis and the derma. Groups or colonies are also evident, and the polymorphism suggests treponemata and leptospirillæ. In the basal cell layer the place of the normal pigment appears to have been taken by the stained organisms. Of greatest interest is their presence and apparent growth along the walls and in the sheaths of hair follicles, where a toxic pilopapillitis explains the resulting hair loss and occasional destruction of the hair follicle. It cannot be definitely ascertained at present whether the cell itself can be penetrated, but it is clear that the pigment-forming cells are highly susceptible, a fact which sustains Sabouraud's original observation that in alopecia areata the ordinary tissue reactions and proliferations are of the slightest. "Toutes aussi concordent à témoigner d'une intoxication locale profonde."

SPECIAL ARTICLES

EDICAL RESEARCH AND PATENT LAW.

UNANIMOUS CONCLUSIONS.

HE conference on medical research and patent , called by the Council of the British Medical ociation, has held two meetings, at the first of ich Dr. R. Langdon-Down, who presided, said t the Association had reached an impasse in its discussion of the principles involved, and was iting the coöperation of others in reaching clusions. The conference was made up of resentatives as follows :—

oyal College of Physicians of London : Dr. ence East, Prof. C. Lovatt Evans, and Dr. Robert tchison.

oyal College of Surgeons of England : Sir Charles don-Watson, Mr. R. G. Hogarth, and Sir Holburt ring.

edical Research Council : Sir Henry Dale, Sir lter Fletcher, and Prof. J. J. R. Macleod.

ritish Medical Association : Sir Robert Bolam, C. O. Hawthorne, Dr. Arnold Lyndon, and Mr. S. Souttar.

t its second meeting (on May 18th) the conference n came to unanimous agreement on four resolu- ns put forward by Sir Henry Dale, Sir Walter tcher, and Mr. H. S. Souttar, which, after some bal amendment, were carried in the following m :

. That this conference is of opinion that the granting further patents in the medical field is undesirable in the lic interest, and would welcome any action to prevent regulate such further grants by international agreement.

. In the opinion of this conference, experience has wn that research and discovery have been hindered her than promoted by the granting of patents for inven- ns dealing with the following classes of substances used therapeutics and practical dietetics : serum, toxins, igens, viruses, bacteriological products, active principles ural to the animal body, vitamins. They consider it irable in the interests of medical science and practice, t no further patents should be granted for inventions ling with the manufacture of such substances for use in dicine or dietetics. If patents are granted for methods manufacturing such substances for other uses, they sider that manufacture for use in medicine should be mpted from the operation of such patents. They would e amendment of the law to secure these ends.

3. The members of the conference are not convinced t the granting of patents for the synthetic preparation new substances, for use in therapeutics, has been similarly rimental. They further appreciate the possibility that ne-sided and purely national abolition of such patents ght unjustly penalise commercial enterprise in this country. ey would gladly see a mechanism established by which tents for inventions in the medical field, other than those ecified in (2), could be dedicated to the use of the public this country, while affording the requisite priority of tion in other countries.

4. Until some such dedicatory system is established, e members of the conference think that the special position ld by medical men in the community renders it undesirable at they should apply for patents in the medical field.

EFFECT OF THE RESOLUTIONS.

The first of these resolutions is a general expression the unanimous opinion of the conference that the tenting of discovery and invention in the medical ld, whether by medical men or others, is not in the blic interest. The second and third suggest a actical means of dealing with a situation which n only be effectively modified by legislative action, hile the fourth defines the line of action which, in e view of the conference, should and can, in existing rcumstances, be taken by members of the profession.

The salient feature of the practical propositions ntained in the second and third resolutions is the distinction made between animal compounds as defined in the second, and synthetic chemical products dealt with in the third. The difference suggested in the treatment of the two groups is admittedly a compromise, but it was felt by the conference to be a wise and practicable one. It was clear that the strongest grounds for complaint against the actual working of the existing patent law in the medical field had been given by patents for the substances described as serums, toxins, antigens, and the like. There was overwhelming evidence that patenting under this head had in practice proved a hindrance to progress rather than that stimulus to research and invention which it is supposed to afford. Even those concerned on the commercial side with substances used in therapeutics and practical dietetics agree in general that the application of such patents has been detrimental to British commerce. Accordingly it was suggested that no further patents should be granted in this group.

On the other hand, it was admitted that in the case of the production of new substances by the processes of synthetic chemistry a stronger case could be made out for the protection of British manufacture by patents similar to those granted in other countries from which rival products were forthcoming. Indeed, while practical experience had shown that for the substances covered by Resolution 2, patents had been an unmitigated nuisance, there was some ground for the view that the progress of synthetic chemistry in Germany had been successfully fostered by patent law. It was therefore suggested that, in connexion with this second group of products some provision might well be made for the dedication of patents to the use of the public in this country without affecting the attainment of the requisite priority of action in other countries. It was realised that to ask the Government to abolish all further patents over the whole of the medical field without reference to the practice in other countries would be useless, however desirable the end in view might be in the opinion of the members of the conference and those whom they represented; but it was felt that the adoption of the distinction explained above should make it possible to obtain some immediate improvement in the existing position.

The memorandum issued by the Medical Research Council[1] was quoted at the conference as having drawn a similar distinction between the substances referred to in Resolutions 2 and 3, and as making out a very effective case for the differentiation now proposed. In support of the distinction, a member of the conference emphasised the point that the knowledge of the processes upon which the introduction of forthcoming products depended was at present so fluid that the only kind of patent which could be obtained under the first head was likely to block further research in that direction. When a process of synthesis having to do with a substance of known constitution was concerned, however, the danger was much less. Blocking patents had been taken out in synthetic chemistry, but to nothing like the same extent.

THE NEXT STEP.

The conference discussed what steps could be taken to make these resolutions effective, and immediate action was deemed desirable, in view of the stage already reached in the progress of the Patents and

Designs Bill through Parliament. For this reason it was agreed that, although the resolutions of the conference are subject to endorsement by the Council of the British Medical Association, they should, as the opinion of the conference itself, be communicated in the meantime to the Ministry of Health, the Board of Trade, and the medical Members of Parliament. They will be submitted, in addition, to the bodies which sent representatives to the conference.

THE BRITISH SPAS:

AN APPRECIATION.

STATEMENT No. 3, issued by the British Health Resorts Association,[1] says that although there are many waters in the British Islands (Dr. Rutty in 1757 described 131 sources of medicinal water in Ireland alone), there are at present only 12 actual spas—that is to say, places where natural medicinal springs are installed in establishments for medical use. The British spas are distinguished from those of the Continent by their invigorating and tonic quality, imparted by the northern island climate. The summer is considerably cooler than at most continental resorts, excepting only those in the Alps. With this temperate quality and the long northern days is combined a freshness and almost incessant movement of the air. The medical value of the northern moorlands of moderate altitude is comparable to that of the Swiss mountains. The influence of the British climate and of latitude profoundly modifies the action of water-drinking and baths, and the reaction of invalids under treatment in fresh and tonic airs is different from that observed in enclosed and sultry valleys. Two main types of spa treatment are practised in England:

(1) The *catabolic type*, which aims at increasing elimination from the body by the bowels, kidneys, and skin, aided by appropriate diet and exercise. This is especially suitable for patients, whatever the form of their particular disorder, who are sedentary, of good appetite, well-nourished and florid, often showing signs of congestion and high blood pressure (*hyperpiesia*).

(2) The *anabolic type* of treatment, which aims at increasing and improving the nutrition of the body by tonic waters, baths, and regimen. This, again, is especially desirable for chilly and ailing or convalescent persons, usually of poor appetite, thin and ill-nourished, pale, with cold and inactive skin and poor circulation (*poikilothermia*).

THERAPEUTIC INDICATIONS.

The medical uses of the British spas are, naturally, not so highly differentiated as in countries where there are many varieties of waters. Fortunately, both these great categories of chronic maladies—the congestive and the subnormal—are well treated at all the British spas. In the north, Strathpeffer, Buxton, and Harrogate offer a frankly tonic summer treatment. Woodhall Spa, to the east, is more sheltered. At the Welsh spas, and at Leamington, Cheltenham, and Droitwich in the Midlands, the tonic and sedative influences are combined. Bath is the warmest and most sedative of British spas, and eminently suited for treatment in winter.

The 12 British spas present an interesting variety.

The hot springs of BATH, rising at 120° F., were used by the Celts and Romans, and there was a Bath hospital in the sixth century. Their diuretic and solvent effects are enhanced by baths of various kinds. Deep pools of thermal water, besides douches and whirlpools, are used for the relief of pain and stiffness in many chronic rheumatic affections, and for the treatment of wasted and paralysed limbs, as well as injuries. The warm winter climate reinforces the effect of the baths.

BRIDGE OF ALLAN, in the Lowlands of Scotland, has been recently rediscovered as a spa. The calcium salt waters are used for rheumatism and by inhalations for catarrh, and the mild and equable climate makes it a resort for all seasons.

BUXTON, in Derbyshire, stands 1000 feet above sea-level, and, like Bath, was known to the Romans. The warm blue waters, from which the name of "The Blue Spa" is derived, have been used for the rheumatic poor since the sixteenth century, and the fine hospital is a lasting monument to their value. Buxton is a natural "Centre of Convalescence."

Both CHELTENHAM and LEAMINGTON, with TUNBRIDGE WELLS (no longer a spa) were fashionable centres for water-drinking 100 years ago. The first, with its uncommon alkaline waters, is especially useful in intestinal and liver disorders. Both are useful salines, in sheltered localities, suitable for spa treatment at all seasons and for delicate and elderly persons and those returned from tropical countries.

The brines of DROITWICH—*Salinæ* of the Romans—are ten times as strong as sea water, and are used externally for many forms of rheumatism, re-educational movements in the bath now forming part of the cure.

HARROGATE, on a bracing Yorkshire moor, has a remarkable outcrop of sulphur, saline, and iron springs, first described in 1626, and has had its excellent spa hospital for more than a century. The spa claims with some justice to counteract the effects of a sedentary life, and especially the disorders of the digestion and liver.

LLANDRINDOD WELLS, in central Wales, has also a pleasant moorland climate, and its "anti-catarrhal" salt waters are of curative value for catarrhs of the stomach and bowels, as well as a tonic in anæmia and debility. The neighbouring LLANWRTYD, too little known, possesses an abundant source of sulphuretted water.

TREFRIW, in Carnarvonshire, is a little-known spa, possessed of a nearly unique acid-iron water. Given in spoonfuls and externally in compresses and baths, it is a powerful stimulant in certain forms of arthritis and anæmia.

STRATHPEFFER SPA, in the Highlands, is the northernmost of the British stations, and has some of the strongest sulphur waters in Europe, as well as an iron spring. The tonic-sedative air is very favourable for repose and recuperation.

WOODHALL SPA, in Lincolnshire, has a dry and bracing air. The salt waters, with a little bromine and iodine, are diluted for drinking and are used externally for rheumatism and diseases of women, and by inhalation for respiratory catarrh.

Altogether the British spas comprise most of the waters which should be of service in preventing ill-health and in relieving the disorders associated with a northern climate.

SPECIALISATION.

No one country contains every natural provision for health. There are no arsenical waters in England, and children and others for whom such waters are considered desirable must be directed elsewhere. Alkaline waters, which are greatly resorted to in other countries, are little used in England.

The British spas have not specialised to the same extent as those on the Continent. For instance, treatment by diuresis (flushing of the kidneys) has not been differentiated and systematised, although there are many available waters which have diuretic properties, such as those of MALVERN, ILKLEY, MATLOCK, BRACEBOROUGH SPA. There is no health resort that is mainly or exclusively concerned with cardiovascular cases with the various procedures recommended for these too prevalent conditions. Treatment in the home country is especially desirable for cases of that kind. Again, there is no spa chiefly devoted to asthma and respiratory affections, although useful methods are now employed at more than one of the British spas. In other countries a spa technique has been developed for these ailments, in which varied modes of treatment are combined—a system of inhalations being used simultaneously with waters and general and local baths.

Many classes of health seekers may confidently expect to benefit by British waters and baths. These lude sufferers from chronic rheumatic disorders, ty manifestations, arterial hypertension, dys- sia and indigestion in their various forms, gestive or catarrhal, whether in sedentary or valescent persons, and from nerve exhaustion and iety states. In addition to these are the many r-tired people, showing signs of strain and failing lth, who need more than a holiday every summer. equate and complete treatment is available for these conditions at the British health resorts.

---

[1] The statement is signed on behalf of the Medical Advisory Committee of the Association by Dr. R. H. Elliot, Sir Thomas Horder, Dr. Robert Hutchison, Dr. E. P. Poulton, Sir Humphry Rolleston, Sir William Willcox, Dr. R. A. Young, Dr. R. Fortescue Fox (chairman), and Dr. W. S. C. Copeman (hon. secretary).

From the international standpoint, therefore, the s of Britain take their place as a group of northern tions. They offer a particular type of treatment, ich, reinforced by the island climate, is more mulant and less sedative than spa treatment on Continent. With this dominant character the ferent members of the group serve a good variety medical uses.

HUGHLINGS JACKSON MEMORIAL MEDAL.

PRESENTATION TO SIR CHARLES SHERRINGTON.

On May 19th, at the annual meeting of the Section Neurology of the Royal Society of Medicine, Stanley Barnes, as president of the section, had e pleasant duty of introducing the first recipient the Hughlings Jackson Memorial Medal. He alled the foundation and history of the lectureship, e first lecture being given in 1897 by Dr. Hughlings ckson himself to the old Neurological Society, d subsequent lectures being delivered at irregular tervals by such men as Hitzig, Broadbent, Horsley, wers, Head, and Dana. About twenty years ago oth had suggested raising a fund to endow the tureship, but no action was taken and the matter s forgotten. In 1931 Sir Charles Sherrington ve the lecture, and at a dinner given in his honour e same evening Mr. Leslie Paton, then president the section, proposed that money should be raised endow a medal and give an honorarium to the cturer. The proposal had an enthusiastic reception d a satisfactory outcome, and that evening they ere in a position to present the first medal and a eque for 100 guineas to Sir Charles Sherrington. r. Barnes noted that among those present was r James Crichton-Browne, Dr. Hughlings Jackson's ldest surviving friend, and called on him to say a w words. Sir James spoke of his first meeting with ackson 70 years ago, of their subsequent association, nd of the early papers published by Jackson in the edical Reports of the West Riding Asylum. When e (the speaker) had to leave Yorkshire, these reports nder his editorship ceased to be published, and he need for some similar journal led to the foundation f *Brain*, and out of *Brain* grew the Neurological ociety, of which Hughlings Jackson was the first resident. Sir James Crichton-Browne recalled ackson less as a great neurologist and physician han as a dear friend. Sir Charles Sherrington had done magnificent work on the lines laid down by Jackson, with advantages for research which Jackson did not possess.

Dr. T. Watts Eden, president of the society, then presented the medal and cheque to Sir Charles Sherrington, and also his diploma as an honorary member of the Section of Neurology. It was appropriate that the work of one of the greatest clinical observers the world had ever seen should be thus commemorated. Sir Charles Sherrington's investigations had disclosed a domain of nerve function which was hardly dreamed of in Hughlings Jackson's time, and the happy association of clinical and experimental work was exemplified on this occasion.

Sir Charles Sherrington, who was received with prolonged applause, expressed his gratitude to the society and to all those at home and abroad who had joined in the inauguration of the medal and had honoured him by this presentation. He spoke of Hughlings Jackson's happiness in being able to combine work in the laboratory with work at the bedside; he, himself, had found it impossible to get far outside the walls of the laboratory, and was all the more appreciative of the fact that they had singled out for this honour one who had been working on a narrow line. The presence of Sir James Crichton-Browne was an added pleasure, inasmuch as he had been a colleague and friend of Hughlings Jackson long years ago.

After Mr. Leslie Paton had presented two replicas in toned silver to Dr. Watts Eden for the Royal Society of Medicine, Dr. Stanley Barnes thanked the treasurer of the fund, Dr. Wilfred Harris, in the name of the Section of Neurology for his work for the fund.

Dr. Harris, in reply, said that when he went up to Cambridge as an undergraduate in 1888, Sir James Crichton-Browne had recently been elected president of the Neurological Society, third in succession from Hughlings Jackson. At Cambridge, under Michael Foster, he found that the third volume of Foster's Physiology on the Central Nervous System, a monumental work, was written entirely by Sherrington. As the students were supposed to know the whole of this for the tripos examinations, he thought of Sherrington in those days perhaps with somewhat mixed feelings. Five years later, after leaving Cambridge, he became Dr. Hughlings Jackson's house physician, and he had always looked on Jackson's and Sherrington's names as meaning more for him in neurology than any others. It would readily be understood, therefore, how intensely interesting it had been for him to aid in gilding the inscriptions of two names indelibly written in the annals of the Section of Neurology.

IMMUNISATION AGAINST DIPHTHERIA.

RESOLUTIONS OF THE LONDON CONFERENCE.

At a conference of 21 experts under the chairmanship of Dr. Th. Madsen, held in London in June, 1931, reports were presented of studies in immunisation against diphtheria carried out on a uniform plan in nine European countries. On the basis of the information submitted to it the conference formulated certain practical conclusions designed to help health administrations in the campaign against diphtheria. The text of these resolutions, which have received the approval of the Health Committee of the League of Nations, is given in the first number of the new *Quarterly Bulletin* as follows :—

1. Immunisation against diphtheria, when carried out under suitable conditions and with efficient prophylactics, effects a large reduction in the diphtheria mortality- and morbidity-rates among children thus treated. This is proved by studies carried out under strictly comparable conditions, such as those observed during the recent inquiries.

2. The reactions sometimes observed after the injection of diphtheria prophylactics give no cause for alarm and

Designs Bill through Parliament. For this reason it was agreed that, although the resolutions of the conference are subject to endorsement by the Council of the British Medical Association, they should, as the opinion of the conference itself, be communicated in the meantime to the Ministry of Health, the Board of Trade, and the medical Members of Parliament. They will be submitted, in addition, to the bodies which sent representatives to the conference.

THE BRITISH SPAS:

HUGHLINGS JACKSON MEMORIAL MEDAL.

PRESENTATION TO SIR CHARLES SHERRINGTON.

May 19th, at the annual meeting of the Section Neurology of the Royal Society of Medicine, Stanley Barnes, as president of the section, had pleasant duty of introducing the first recipient he Hughlings Jackson Memorial Medal. He lled the foundation and history of the lectureship, irst lecture being given in 1897 by Dr. Hughlings son himself to the old Neurological Society, subsequent lectures being delivered at irregular vals by such men as Hitzig, Broadbent, Horsley, ers, Head, and Dana. About twenty years ago h had suggested raising a fund to endow the ureship, but no action was taken and the matter forgotten. In 1931 Sir Charles Sherrington the lecture, and at a dinner given in his honour same evening Mr. Leslie Paton, then president e section, proposed that money should be raised ndow a medal and give an honorarium to the urer. The proposal had an enthusiastic reception a satisfactory outcome, and that evening they in a position to present the first medal and a ue for 100 guineas to Sir Charles Sherrington. Barnes noted that among those present was James Crichton-Browne, Dr. Hughlings Jackson's st surviving friend, and called on him to say a words. Sir James spoke of his first meeting with son 70 years ago, of their subsequent association, of the early papers published by Jackson in the ical Reports of the West Riding Asylum. When the speaker) had to leave Yorkshire, these reports er his editorship ceased to be published, and need for some similar journal led to the foundation *Brain*, and out of *Brain* grew the Neurological ety, of which Hughlings Jackson was the first ident. Sir James Crichton-Browne recalled kson less as a great neurologist and physician as a dear friend. Sir Charles Sherrington had e magnificent work on the lines laid down by son, with advantages for research which Jackson not possess.

r. T. Watts Eden, president of the society, then ented the medal and cheque to Sir Charles rrington, and also his diploma as an honorary nber of the Section of Neurology. It was appropriate t the work of one of the greatest clinical observers world had ever seen should be thus commemorated. Sir Charles Sherrington's investigations had disclosed a domain of nerve function which was hardly dreamed of in Hughlings Jackson's time, and the happy association of clinical and experimental work was exemplified on this occasion.

Sir Charles Sherrington, who was received with prolonged applause, expressed his gratitude to the society and to all those at home and abroad who had joined in the inauguration of the medal and had honoured him by this presentation. He spoke of Hughlings Jackson's happiness in being able to combine work in the laboratory with work at the bedside; he, himself, had found it impossible to get far outside the walls of the laboratory, and was all the more appreciative of the fact that they had singled out for this honour one who had been working on a narrow line. The presence of Sir James Crichton-Browne was an added pleasure, inasmuch as he had been a colleague and friend of Hughlings Jackson long years ago.

After Mr. Leslie Paton had presented two replicas in toned silver to Dr. Watts Eden for the Royal Society of Medicine, Dr. Stanley Barnes thanked the treasurer of the fund, Dr. Wilfred Harris, in the name of the Section of Neurology for his work for the fund.

Dr. Harris, in reply, said that when he went up to Cambridge as an undergraduate in 1888, Sir James Crichton-Browne had recently been elected president of the Neurological Society, third in succession from Hughlings Jackson. At Cambridge, under Michael Foster, he found that the third volume of Foster's Physiology on the Central Nervous System, a monumental work, was written entirely by Sherrington. As the students were supposed to know the whole of this for the tripos examinations, he thought of Sherrington in those days perhaps with somewhat mixed feelings. Five years later, after leaving Cambridge, he became Dr. Hughlings Jackson's house physician, and he had always looked on Jackson's and Sherrington's names as meaning more for him in neurology than any others. It would readily be understood, therefore, how intensely interesting it had been for him to aid in gilding the inscriptions of two names indelibly written in the annals of the Section of Neurology.

IMMUNISATION AGAINST DIPHTHERIA.

RESOLUTIONS OF THE LONDON CONFERENCE.

At a conference of 21 experts under the chairmanship of Dr. Th. Madsen, held in London in June, 1931, reports were presented of studies in immunisation against diphtheria carried out on a uniform plan in nine European countries. On the basis of the information submitted to it the conference formulated certain practical conclusions designed to help health administrations in the campaign against diphtheria. The text of these resolutions, which have received the approval of the Health Committee of the League of Nations, is given in the first number of the new *Quarterly Bulletin* as follows :—

1. Immunisation against diphtheria, when carried out under suitable conditions and with efficient prophylactics, effects a large reduction in the diphtheria mortality- and morbidity-rates among children thus treated. This is proved by studies carried out under *strictly* comparable conditions, such as those observed during the recent inquiries.

2. The reactions sometimes observed after the injection of diphtheria prophylactics give no cause for alarm and

should not interfere with the campaign for the immunisation of children, including tuberculous children, nor should they prevent the choice of the most active prophylactics.

3. The conclusion appears justified that, in spite of a few exceptional cases, the efficacy of immunisation may be deduced from the change of the Schick reaction from positive to negative.
4. Taking as a basis the figures concerning the morbidity, the percentage of Schick reaction rendered negative after the injection of the immunising agent, and a certain number of titrations of antitoxin in the blood of persons immunised, it may be concluded that formol toxoid (anatoxin) is the most efficient of those antigens which have been the subject of our comparative study—i.e., mixtures of toxin, antitoxin, and formol toxoid (anatoxin), and should be recommended for the present.
5. The clinical observations submitted to the conference indicate that, so far as can be determined up to the present, the immunising power of formol toxoid (anatoxin) in man appears to be in relation with the antigenic value of the prophylactic as measured by the flocculation method.
6. The method of administration recommended is by subcutaneous injection. When this is not possible, the prophylactic may be applied to the nasal mucous membrane. Our experience with the cutaneous method has not been favourable.
7. Immunisation should be carried out by means of three injections. *It is hoped that, in the future, the use of a more active prophylactic will make it possible to immunise with two or perhaps even one injection.*
8. The intervals recommended between injections are three weeks between the first and second injection, and at least two weeks between the second and third.
9. It is unnecessary to carry out the Schick reaction before immunisation. It is, however, desirable to use the Schick reaction before and after immunisation in a certain proportion of subjects in order to determine the value of the method employed.
10. It is recommended that immunisation against diphtheria should be carried out not later than during the pre-school period, after the end of the first year of life. If the children have not been immunised during the pre-school period, *they should be immunised, if possible, during the first year of school attendance.*
11. Charitable organisations and administrations receiving children in homes (holiday camps, preventoria,[1] sanatoria, &c.) are advised to require, from both children and staff, a diphtheria immunisation certificate on admission or a certificate attesting that the Schick reaction was negative.
12. Immunisation is recommended for medical, nursing, and domestic staff in hospitals, homes, dispensaries, sanatoria, schools, &c.
13. Immunisation is to be recommended even during epidemics in the case of children who have been in contact with patients, as there is so far no evidence on record as to the existence of a *negative phase.*
14. In the opinion of the experts, diphtheria immunisation should form the subject of active public education on the part of the health administrations of the different countries in order to bring home to everyone the advantages of this method of protection in safeguarding the public health.

These resolutions, it is stated in an introductory paragraph, being the logical outcome of lengthy investigations carried out concurrently in several countries, represent an international consensus of opinion, and constitute a doctrine which, in view of the qualifications of its authors, may be regarded *as established.*

MEDICINE AND THE LAW.

Highgate Hospital Inquiry.

ON April 21st the Central Public Health Committee (No. 1) of the London County Council had its attention drawn to an article in *John Bull* reflecting upon the admission and treatment of a patient in Highgate Hospital. The article contained complaints of the treatment of the patient at his reception, delay in the attendance of a hospital doctor, persecution of the patient with questions about his personal history, wrong diagnosis, acute suffering of the patient from thirst and want of nourishment, unsuitable diet, failure to notify the patient's wife of her husband's *serious condition,* and the fact that a letter was sent to him after his death. The article seems to have set these allegations forward as a grave indictment of the general administration of municipal hospitals.

The Committee appointed a subcommittee to examine the charges. The widow had previously called at the County Hall and made complaints; she then said she would attend the inquiry, but, although invited to do so, she did not in fact attend. The subcommittee made a thorough investigation of the allegations and expressed the opinion that the facts elicited afford no justification whatever for the reflections made in the published article on the organisation and administration of municipal hospitals. While space does not permit detailed analysis of the separate complaints and the relevant findings, the suggestion of wrong diagnosis may perhaps be cited as a sample.

The article said the patient was unquestionably suffering from acute pneumonia, and that the family doctor's order for his reception was signed to that effect with an added query as to the possibility of tuberculosis; that the hospital doctor ordered the patient, though certified to be suffering from pneumonia, to be taken to the tuberculosis ward; and that the widow protested and insisted on a post-mortem examination, whereupon the cause of death was certified to be pneumonia. The subcommittee find that the family doctor's certificate said the patient was suffering from broncho-pneumonia (tuberculous) and that there was no query. On this and his past history he was placed in the tuberculosis ward. His history was that he was certified suffering from tuberculosis of the lungs in 1927 and was then treated at Colindale Hospital, Hendon; he suffered from hæmoptysis in 1931 and was treated at St. Joseph's Hospice, Hackney; during 1928, 1929, 1930, and 1931 he was under the care of the tuberculosis officer at St. Pancras dispensary. The medical superintendent at Highgate described an interview with the widow at which she had said she thought his illness was probably not tuberculosis; she had had him insured lately and would not be able to get the money if tuberculosis appeared on the certificate. The post-mortem inquiry did not disclose tuberculosis as a cause of death. The primary cause of death was lobar pneumonia, the secondary cause was *cardiac syncope.* Part of the allegation as to unsuitable diet was that the patient was offered boiled mutton instead of jelly and custard. The subcommittee says that he was given lemon water, beef tea and milk, and a little custard and jelly; boiled mutton was not included in the hospital diet on any of the days in question.

The Committee is to be congratulated on its prompt and proper action and the hospital management on its complete vindication. If the truth receives the same publicity as the charges, perhaps no great harm will have been done.

Sale of Izal by Grocer: Unsuccessful Proceedings.

One of the points reported upon in *1930* by the Departmental Committee on the Poisons and Pharmacy Acts was the inclusion in Part II. of the present Schedule of Poisons of "carbolic acid and liquid preparations of carbolic acid and its homologues containing more than 3 per cent. of these substances." The Committee observed that the interests of public health demanded the use of effective disinfectants, but that the average purchaser for domestic and ıdred purposes, instead of going to a chemist's op and buying a really effective article which ecause it is a poison) he cannot get elsewhere, clines to buy from a grocer or general dealer an ferior article bearing perhaps the same or a similar me, not a "poison," but one which as a disinfectant inefficient in fact. This was a point which had been rongly urged on the Committee by the Society of edical Officers of Health. A wider issue, of course, the loss of the public safeguard which was broken wn when under the Act of 1908 the sale of poisons the public ceased to be solely in the hands of rsons qualified in skill and knowledge. It was a fect of the Committee's recommendations that ey would apparently have multiplied the unqualified llers of the raw material of murders and suicides by owing any person to be a licensed seller who was t positively of bad character or unsound mind.

---

[1] i.e., institutions for delicate children.

The Pharmaceutical Society, to whose honourable cord of service the Committee paid tribute, does its st to enforce laws which are none too clear. It kes action (under Section 15 of the Pharmacy Act, 68) against anyone who, not being a duly registered armaceutical chemist, or chemist or druggist, sells poison to which the Acts apply. The Society thus ok proceedings lately against a Hounslow grocer selling the disinfectant Izal, a liquid preparation phenol and a homologue of carbolic acid. Such mologues are included in Part II. of the list of tutory poisons in the terms already quoted; but ere is an express exception in favour of "preparans for use as sheep wash or for any other purpose connexion with agriculture or horticulture, conined in a closed vessel distinctly labelled with the rd 'Poisonous,' the name and address of the ler, and a notice of the special purposes for which e preparations are intended." There was no doubt at Izal came within the description of carbolic acid mologues containing more than 3 per cent.; there s no doubt that, as sold, it was contained in a sed vessel properly labelled. The sole question the Hounslow case was whether it was a preparation use as sheep wash or for an agricultural or hortiltural purpose. There was evidence that the effield manufacturers packed Izal in bottles in a rton described as "Pharmacists' Pack" when the id was to be sold by chemists for domestic use; ey packed it in something called the "Universal ck" when it was to be sold by grocers for agriltural or horticultural purposes. In the latter case e label satisfied the statute by saying "for use in riculture and horticulture: for general purposes d to a pail of water two tablespoonfuls of Izal." e Brentford county court judge held that the eparation was duly sold with a notice that it was r use in agriculture or horticulture, and that specific stances of its use as such were given; consequently e preparation came within the statutory exception, d the Acts had not been broken. For the Pharmautical Society it was argued that the court must ok at the real object of the sale; if the sale was in ct for a purpose which was neither agricultural nor rticultural, the labelling ought not to protect the qualified seller. The King's Bench Division, wever, has rejected this argument and has refused look at the exact purpose for which the bottle as sold. If the label was a mere sham, there might an offence against the Acts; but there was no idence of any such fraud in the present case. The igh Court upheld the county court, and thus the harmaceutical Society, seeking to do its duty under e Acts, is foiled.

ANTIGEN-BASED TESTS IN THE DIAGNOSIS OF NEMATODE INFECTIONS.

EARLY last year we commented on work by N. Hamilton Fairley and F. Jasudasan[1] which brought out the value of complement fixation in the diagnosis of schistosomiasis in animal and man. In this infection the complement-fixation reaction to antigen is of the group type and the source of antigen advised by these writers was snail liver heavily infected with the cercaria of *Schistosoma spindalis*. A heavy infection is necessary so that the test material may contain as much cercaria and as little liver as possible. In this connexion it is worth noting that it is indeed possible, should necessity arise, to obtain cercariæ almost free from liver by grinding and washing this and collecting the live cercariæ which escape from it, that in this way an almost pure cercarial antigen can be obtained from a lightly infected liver, and that the precipitin reactions produced by it are reported as being stronger, clearer, and more specific than are those from whole liver.[2] The obtaining of an almost pure antigen from a worm in a stage of development in which it is embedded in the host's tissues was anticipated by Ströbel[3] in 1911 when he freed trichinæ from infected meat by digestion with pepsin and hydrochloric acid. Using this principle Bachman[4] was able to obtain the living larvæ of *Trichinella spiralis* so free from other matter that the fluid containing them gave no biuret reaction.

THREE TYPES OF TEST.

In nematode infections three of the antigen-based tests repay consideration—namely, precipitin, intradermal, and complement fixation.

Precipitin reactions were secured by Bachman in trichinosed animals, using the antigen obtained as just described; but precipitins did not appear in the serum of infected rabbits until about 30 days after infection, by which time, as he points out, human cases are either dead or convalescent. Nevertheless, in these particular experiments the antigen was specific in the sense that in course of time every infected animal showed precipitins if it lived long enough, while no control ever did so. In contrast with this positive reaction in the case of a nematode which passes much of its life in tissues are the findings of Coventry for ascaris[5] and Stumberg for hookworms[6]; they could detect no parallelism between infection with these intestinal parasites and precipitin reactions with extracts of the respective adult forms. At present it cannot be said that precipitin reactions interest the practising medical helminthologist.

Intradermal reactions both immediate and delayed, the latter long since associated with Casoni's name in hydatid infection, have application in certain nematode infections. For *Strongyloides stercoralis* Fülleborn[7] has applied by the scratch method an antigen obtained from the dried bodies of the filariform larvæ and has found an immediate reaction in the infected, whereas in the uninfected there is none unless their skin shows a general sensitiveness to foreign protein. From the clinical standpoint he finds an interesting parallel between the itching perianal swellings which occur in those infected by this parasite and the papule which follows the application of an infective larva to the skin; and he suggests that the former are due to penetration of the skin by larvæ which have developed to infectivity in microscopic portions of fæces sheltered in the depths of perianal folds, and that this supposition goes far towards explaining the persistent character of this infection. Examination of sections of the wall of the small intestine suggests that the habitat of the nemidia of this parasite is not limited to the lumen of the gut, but that it invades the lymph-bathed tissue of the mucosa itself. For parasites of the lumen of the gut (hookworm, ascaris, and trichuris) Coventry and Taliaferro [8] have found no relationship between such infections *and immediate intradermal reactions to antigens* made from the bodies of the respective parasites. Yet, for delayed reactions, Coventry [5] noted their occurrence in laboratory animals infected with or sensitised to ascaris, but not in controls; while the possibility of producing this reaction persisted for months, it did not run parallel to the precipitin reaction. That however it is not evidence of present, and probably not even of past, ascaris infection was indicated by Ransom, Harrison, and Cough,[9] whose experience led them to the conclusion that at least in laboratory workers it was an occupational condition, *capable of being produced in those whose occupation* brought them into contact with the parasite but who were not necessarily infected by it.

These findings suggest that antigen-based tests *for nematodes will mainly prove effective in those* infections in which the parasite lives in plasma or lymph, and there is evidence for this conclusion in work done during the last two years on the filaria group. Taliaferro and Hoffman [10] used as an antigen an extract in normal saline of dried and powdered *Dirofilaria immitis*, a filaria which lives in the heart cavities of the dog, and concerned themselves essentially with the immediate intradermal reaction after injection of the equivalent of 0·000125 g. of dried worm. This is a tenth of the amount of antigen, expressed as snail's liver, injected in the same strength as was used by Fairley and Williams [11] when they instituted *the intradermal method for the detection* of schistosome infection, the change apparently being made because the American workers considered that it appeared to be the concentration rather than the quantity of antigen which determined the severity of the reaction. This was held to be positive if the resulting wheal were 5 mm. in diameter or if one of any size possessed outrunners or pseudopodia, provided always that concomitant injections of snail's liver or of saline showed no such characters. As thus defined a positive result was obtained in 22 of 23 persons who at the time had micro-filariæ in their blood, and in two of 19 who had never been in an endemic area. They added, regarding delayed reactions, that these followed in five of the 23 who were certainly infected, in two of 39 who were possibly infected, and in none of 43 who were probably or certainly uninfected.

The matter has been carried a step further by Hamilton Fairley [12] who used both intradermal and *complement-fixation tests for infections with members* of the filaria group. By one of those not infrequent coincidences he, too, selected *D. immitis* to furnish his antigen, though his work was conceived and started in complete independence and without knowledge of that of Taliaferro and Hoffman. The antigen was a 2 per cent. alcoholic extract. In all of seven cases actively infected with loa, showing that is recent Calabar swellings and a high eosinophilia, complement fixation was positive in dilution of from 1 in 100 to 1 in 800. *It was also positive in* four persons believed to be infected with *F. bancrofti* —one, that is to say, had a clear history of filarial hydrocele and the three others had lived for many years in endemic areas. Negative reactions were obtained in 59 controls suffering from various diseases and parasitised with various other worms; they indeed included two cases of hydatid of the liver and two of infection with *Schistosoma hæmatobium* which gave strong reactions respectively with hydatid scolex and cercaria. Of these 59 cases three had evidence of old infection with *F. bancrofti* in that dead worms were excised from two of them, while the *third gave a history of lymphangitis* with microfilariæ in the blood a year earlier; but none of them showed microfilariæ at the time of examination. In addition one from whom an onchocerca nodule had been removed showed a weak positive reaction.

VALUE OF THE REACTIONS.

Apart from some carried through with negative results by Fairley and Glen Liston [13] in 1924 in guinea-worm infection, complement-fixation tests do not seem hitherto to have been applied to lymph-dwelling nematodes, but the positive findings now *reported in loa cases where living worms were certainly*, and in *F. bancrofti* cases where they were probably, present, taken in conjunction with the negative ones in which they were probably not present, must *lead to coördinated* serological and pathological study of a test which promises to be a valuable aid to diagnosis.

This conclusion is confirmed by the results of Hamilton Fairley's intradermal tests in which, at least latterly, the amount of antigen used was 0·00025 g. In all the seven loa cases there was an immediate reaction, as there was too in six of the seven cases known or suspected to harbour *F. bancrofti*. The exception had gastric carcinoma, positive complement fixation in a dilution of 1 in 800, a heavy eosinophilia, had lived for long in an endemic area, but had no detected evidences of filarial infection. *In these tests a positive reaction* was one in which the immediate wheal, including pseudopods, measured not less than 2·3 cm. and in which control injections were negative. Delayed reactions added themselves to the immediate ones in all the loa and in several of the *F. bancrofti* infections; and the resemblance of these deep blubbery swellings to Calabar swellings was a matter of comment by the loa patients who were thoroughly familiar with these latter in their own persons. In character they differ completely *from the initial wheal, but the delay* in their appearance need not be great; for instance in a case reported by A. C. Chandler, G. Milliken, and Schuhardt [14] Calabar swellings appeared within 20 minutes of an operation in which a loa was removed from the conjunctiva and was probably injured in the process, and in Fairley's cases this reaction sometimes appeared within an hour of intradermal injection. In the onchocerca case both immediate and delayed reactions were elicited. Fairley points out that the complement-fixation and intradermal tests supplement one another, since the first detects circulating antibody and affords an index to more active infection; while the latter detects the intracellular antibody which may persist long after circulating antibody and even the parasites themselves have disappeared, and does so whether the antigen remains limited to the dermis as in the immediate wheal, or diffuses into the subcutaneous tissue as in the delayed reaction. He points out too that since microfilariæ are not demonstrable for years after infection with *Loa loa* has taken place while Calabar swellings appear earlier, intradermal injection may allow of yet earlier detection, while it provides an entirely new mode of approach the study of infection with *F. bancrofti*. Taken in junction with the anatomical studies which are ng made by O'Connor,[15] the prospects of further l early additions to knowledge of filariasis seem re promising than has for long been the case.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

E IRISH FREE STATE BUDGET AND MEDICAL SUPPLIES.

T is a fortnight since the Minister for Finance ned his Budget, and it is only now that the plications of several of the new customs duties unfolding themselves. For example, the real aning of the "package tax" was not grasped at st. It was known that a tax of 2*d*. was imposed every closed packet or bottle ready for sale which s imported to the country. It was not realised, wever, that the tax was to be levied on every gle packet or bottle in each parcel. Take the case a box containing, say, 12 ampoules of some drug t up ready for use. The tax on such an article ll be 2*s*.; that is to say, each ampoule has to ar a tax of 2*d*. This will be a serious matter, t only for the practitioner, but for the general spital. The use of ampoules has increased ormously in recent years, and will increase more in future as intravenous and hyperdermic methods of dication are developed. Even a small hospital ll find its drug bill much swollen by the duty now posed. The duty is all the more irritating as it es not tend to protect any Irish industry, and the sh trade is hardly considerable enough to induce y of the big manufacturing firms to establish cking-stations in the Irish Free State.

THE PROBLEM OF THE DUBLIN HOSPITALS.

Mr. John Good, an experienced hospital governor d a member of the Dáil, speaking recently at the nual meeting of the Adelaide Hospital, reverted the question of the amalgamation of the Dublin spitals. He recalled that some years ago a move-ent was set on foot to amalgamate the hospitals, project which would have made for efficiency and onomy. The scheme was dropped because the nsiderable sum required to finance it was not then ailable. Now large sums of money were available, it there did not seem to be the same interest in nalgamation as formerly. He hoped that the atter would again receive the attention of the rious hospitals.

The question is, indeed, urgent. The desirability amalgamation is not only obvious but admitted. he money is, or will be in another year or two, available. But there is every likelihood of its being spent in undertakings which will act as a direct obstacle to amalgamation. Every new wing built, every addition to or improvement made in existing buildings, will not merely spend the money which ought to be devoted to amalgamation, but will act as a deterrent. The hospitals are, in fact, "digging themselves in" in their present positions, and tending to give a new lease of life to a system which is outworn and should be obsolete.

THE ASSOCIATION OF PHYSICIANS.

The annual meeting of the Association of Physicians of Great Britain and Ireland was held in Dublin on May 13th and 14th. The Association had not met in Dublin since 1909. The president for the year is Prof. T. G. Moorhead, of Dublin. About one hundred members were present, and it is stated that the meeting was pleasantly successful on both the scientific and the social sides.

AUSTRALASIA.

(FROM OUR OWN CORRESPONDENT.)

THE HOME OF THE COLLEGE OF SURGEONS.

AT the first annual general meeting of the Royal Australasian College of Surgeons held in Canberra, it was suggested that Canberra, being the home of the Commonwealth, should be the home of the College. The Government of the Commonwealth of Australia made a grant of land on condition that it should be accepted within a certain time by the College. It soon became evident that a headquarters at Canberra, although it might have had certain advantages, had many practical objections to it. The matter was further considered, and at the annual general meeting held in Sydney in 1931, it was unanimously agreed that the building of the College should be in Melbourne. This decision was a tribute to the fact that the lion's share of the work of establishing the College, maintaining it and bringing it up to its present high standard, had been done by Melbourne men.

By arrangement with the Government of Victoria, the College has now secured the site of the old Melbourne High School in Spring-street, Melbourne, for which a lease has been granted for a term of years at a nominal rental, on condition that a suitable building shall be erected on the site within a specified time. It is proposed to demolish the greater part of the present building, but retain the architectural features facing Albert-street, and to erect additions which will permit of accommodation for lecture rooms, library, laboratories, museum, and administrative offices. The area of the site is approximately two acres. A condition of the lease provides that, apart from the land required for the building of the College, the whole of the area shall be laid out in gardens, and be available to the public. It is understood that the erection of the building will shortly be undertaken.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

"ECONOMY."

THE bad financial situation of the Austrian exchequer has had unexpected repercussions on the conditions of the staff of the University of Vienna. At present, several important directorships of institutes and clinics are unfilled. These include the first clinic of medical pathology and materia medica, formerly held by Prof. Wenckebach. Leading physicians in Germany who have been offered this appointment have all refused, owing to the unsatisfactory salary and limitations on the conduct of private practice, and several Austrian physicians were approached. They too refused nomination, and the officials of the Ministry of Education, in whose hands the appointment rests, have resolved to save money by continuing the interim arrangement whereby the clinic is in charge of the late first assistant. The same sequence of events occurred in connexion with the first surgical clinic made vacant by the death of Prof. Eiselsberg. The man who would be his most natural successor, Prof. Clairmont, of Zürich, would not be welcomed by all parties to the appointment, and it is likely that in time some less prominent surgeon from one of our provincial clinics will be preferred. Meanwhile, the first assistant—a young surgeon—manages the clinic. Students are thus flocking to the second surgical clinic under Prof. Denk. His lecture theatre holds only 250 students, but 450 have entered their names to attend his lectures and try to squeeze into the crowded hall. The first clinic for diseases of women and obstetrics has remained vacant for quite a long time. Prof. Halban, an international authority, was nominated and nearly appointed. But antisemitic influences were strong enough to prevent his final appointment at the very last moment. Here again a young assistant manages the clinic at a considerable saving of expenditure. The institute for experimental pathology now in abeyance for several years will not be revived although there are several men fully qualified to be its director. The Central Röntgen Institute has become vacant through the death of Prof. Holzknecht. Instead of offering this appointment to a leading authority, who would organise a proper X ray school, and perhaps continue the world-wide attraction which this institute provided during Holzknecht's life, the officials are looking for a good "specialist" who will do the work for less remuneration and who will not be pensionable. Finally, the chairs of anatomy and normal histology are waiting for their occupants. The longer these posts remain vacant or are filled by men of little distinction, the more money is saved, but the students suffer, and, indeed, the prestige of the university. In medical circles this most unsatisfactory tendency is bitterly resented, and in a memorandum to the Government now in preparation, it will be pointed out that a really prominent teacher or clinician draws so many students and patients to Vienna that his higher salary is more than counterbalanced by the stream of money directed to the city by his work.

ASSASSINATION OF PROF. ALEXANDER.

Prof. Dr. Gustav Alexander, the world-famous otologist, was shot to death in front of his home by a former patient, undoubtedly a maniac. It appears that this famous surgeon had performed a cosmetic operation on the man 27 years ago. The patient had been suffering from depression of the bridge of the nose following syphilis, and desired to be freed from his disfigurement. He was not satisfied with the cosmetic effect of the operation, and as long as 22 years go he attempted to shoot Prof. Alexander. The attempt failed; the man was placed in a lunatic asylum and afterwards discharged. A few days ago he returned to Vienna with the intention of killing the surgeon and this time he succeeded. Prof. Alexander was only 57 years old. Already as a student he devoted his attention to the anatomy of the ear and the labyrinth, and he published at an early age several important papers dealing with the finer anatomy and histology of the inner ear and the cochlea. He became assistant to Pollitzer, then chief of the Otological Clinic of Vienna, and later succeeded Urbantschitsch as chief of the ear department in the Vienna Poliklinik. There he founded the Alexander School of Otology, a sort of Mecca for all surgeons studying otology in Vienna. His researches on the labyrinth of white (Japanese) mice, and of the echidna won him the gold medal of the French Otologic Society in 1904. He investigated also the problems of deaf-mutism, of heredity of pathological ear conditions, statics and equilibrium, and published standard works on various branches of his specialty. Cosmetic surgery of the ear and the auricle was only one of the branches in which he excelled. His death is a serious loss to the Faculty.

DEATH OF PROF. ERWIN LAZAR.

The well-known specialist on psychology of the pathologic child, Prof. Dr. Erwin Lazar, has died after a short illness in his fifty-fifth year. He was the originator of modern methods of dealing with the mentally defective or delinquent child, and was the first to emphasise the influence of environment and education on behaviour, and to show how such children could be made useful members of society. In the Pirquet Clinic for Children he organised a special department for refractory children, and later he took over the supervision of all such departments in Austria in the capacity of consultant. Dr. Lazar's classes on "Heilpaedagogik" (curative education) have become famous, and pupils from all parts of the world have been attending his clinic to learn his system of classification of the mentally or emotionally diseased child.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDE DEC. 14TH, 1932.

Notifications.—The following cases of infectiou disease were notified during the week:—Small-pox 76 (last week 68); scarlet fever, 1558; diphtheria 691; enteric fever, 36; acute pneumonia (primary o influenzal), 954; puerperal fever, 60; puerpera pyrexia, 115; cerebro-spinal fever, 49; acute polio myelitis, 5; encephalitis lethargica, 13; continue fever, 2; dysentery, 13; ophthalmia neonatorum 101. No case of cholera, plague, or typhus feve was notified during the week.

The number of cases in the Infectious Hospitals of th London County Council on May 17th–18th was as follows Small-pox, 116 under treatment, 4 under observation (las week 109 and 6 respectively); scarlet fever, 1559; diph theria, 1315; enteric fever, 6; measles, 2614; whooping cough, 420; puerperal fever. 15 (plus 5 babies); encephaliti lethargica, 228; poliomyelitis, 3; "other diseases," 8 At St. Margaret's Hospital there were 13 babies (plus mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including Londo there was no death from small-pox or enteric feve 81 (33) from measles, 4 (0) from scarlet fever, 43 (1 from whooping-cough, 31 (4) from diphtheria, 52 (1 from diarrhœa and enteritis under two years, an 43 (5) from influenza. The figures in parentheses ar those for London itself.

Liverpool reported 11 deaths from measles, Leeds Sheffield 3. Six fatal cases of whooping-cough were reporte from Liverpool and 3 from Nottingham. Diphtheri accounted for 5 deaths at Manchester, 4 at Liverpool an 3 at Hull.

The number of stillbirths notified during the wee was 336 (corresponding to a rate of 46 per 100 total births), including 55 in London.

GENERAL MEDICAL COUNCIL.

PRESIDENT'S ADDRESS.

N opening the 135th session on May 24th, Sir RMAN WALKER, the President, spoke with regret the retirement from the Council of Sir Ashley ckintosh, Sir Holburt Waring, and Sir Hilton ung. He welcomed Sir John Marnoch, Mr. K. Steward, and Mr. Douglas Hacking, M.P., o were taking their places, and he congratulated Henry Dale upon the knighthood conferred on ı since the last meeting.

OLD PROBLEMS AND NEW.

Examination of minutes and presidential addresses wed, said Sir Norman, that "not a few of the blems with which our predecessors wrestled 50 rs ago are remarkably like those with which are confronted to-day." In 1887, after the passing the 1886 Act, Sir Henry Acland had said :—

> Vhen the Council originally met in 1858 there was a eral feeling that the first thing to be considered was mode of improving the general education of the student.

'We cannot to-day speak of that sentiment in past tense," said Sir Norman, "when in the very r future we shall be again considering the education the student before he officially begins the study medicine. Again, here is what Sir Henry said in 7 about preventive medicine :—

> new significance attaches now to the old words "salus uli, suprema lex." Any system of medicine which uld ignore duty to the masses as well as to the individual iow no medicine at all; yet most here can remember time when "polypharmacy" practised sometimes in plicity, often for the sake of lucre, was not uncommon. ne of us can recall the day when the prevention of disease considered almost outside the province of an orthodox lical man.

ınd another of our problems this week is the ısideration of the question whether we are doing all can and ought in the teaching of that subject. it must always be. Circumstances change, and we do not adapt medical education to the changes dical education and the public will suffer."

RECIPROCAL RELATIONS.

"In July of last year the Privy Council transmitted the observations of the Council a copy of the text a Bill to modify the law concerning medical study d practice in France. The observations of the ecutive Committee were to the effect that it was eady far easier for a Frenchman to become a alified practitioner in this country than it was for a eigner to attain similar rights in France. But present tendency of every country to raise its undary walls and to narrow the gates in them has evailed, and the Bill has passed the Chamber, is w before the Senate, and is likely to become an t. Those now practising in France are exempted om its provisions, but those who in future desire to actise in France will be required to pass the baccaureats in, among other subjects, Latin and Greek, the subjects in the medical curriculum, and to come naturalised French citizens.

"The difficulties which arose over the very large mbers of American citizens seeking entry to the dical schools of this country have, thanks to the operation of responsible authorities in the United ates, almost disappeared."

INDIA.

"I wish I had better news to give about medical ogress in India. When a political situation is disturbed, plain useful things like Medicine are apt to be pushed on one side. I had hoped that a peaceful settlement of the question of Indian medical standards and qualifications would have been reached before other trouble arose, and often, in the light of my Indian experience, think wistfully of how nearly that was achieved. The Draft Bill to establish a Medical Council for British India was, at the instance of the India Office, considered in November last by the Executive Committee, who passed the following resolution :—

> The Executive Committee have considered the Draft Bill and the accompanying communications from the India Office, and recognise with satisfaction that it represents a well-directed effort to establish by statute a body which by its constitution and functions is designed to maintain a satisfactory minimum standard of medical qualification for admission to the proposed Indian Register. The Executive Committee are of opinion that, if carried into law, the Bill will conduce to the improvement of Indian medical education, and serve the best interests, both internal and external, of Indian medicine in general.

"Pressure of other business prevented the Government from finding time for the discussion of the Bill at the Delhi Session of the Legislative Assembly, now closed. It is only fair to recall that in most countries it takes time to get a medical Act through Parliament. It took about 50 years of discussion and negotiation to secure the passing of our Act of 1858."

EXAMINATIONS AND REPORTS.

"The present cycle of inspection of the final examinations in medicine, surgery, and midwifery, under the 1886 Act will be completed in June. It will have occupied a little over two years . . . It will be the Council's duty to consider whether in the light of the reports any modification in the curriculum and examinations should be recommended to the licensing bodies. In November, 1920, in connexion with the last cycle of inspection, the Council authorised the Education Committee to set up, under the auspices of the three branch councils, subcommittees to report on the four sections of the medical curriculum. On these subcommittees there sat as coöpted members experts on the different subjects concerned, and useful reports were submitted by all. This method had the merit of enlisting the interest of the medical schools and licensing bodies in the proposals made, and much useful constructive criticism was forthcoming."

"The Education and Examination Committees will jointly present reports on two matters of urgent public importance (maternal mortality and the methods of teaching preventive medicine) which have been under consideration for some time."

"The British Pharmacopœia 1932 is approaching completion, and is expected to be ready for official publication on Sept. 30th."

"The Executive Committee received at their meeting in February a communication from the Medical Research Council concerning patent law. The attitude of the medical profession in this country has always been averse to the patenting of any remedy which might be directly useful to the public, and the patenting of insulin, in the public interest, by the University of Toronto has been generally approved because it was felt that the control of that remedy was essential, and that it was in safe hands. Now, however, a new question has arisen in respect of the patenting of processes used in medical research, and this it is represented is hindering the advance of medicine. This is obviously not in the public interest, and the members of this Council as well as nearly all the members of the profession of this country will, there is no doubt, be in wholehearted sympathy with the proposals which the Medical Research Council has made for solving the difficulty which has arisen.

"Nearly all my predecessors have commented on the responsibilities which rest on the shoulders of the President during the intervals between the sessions. There seems to be an unending stream of problems to settle. I think what has distressed me most is the number of complaints about irregular certificates. I do not propose to discuss the subject to-day. I will just say this: If every practitioner would read carefully the precise terms of every document to which he is asked to put his signature, there would be fewer complaints."

PANEL AND CONTRACT PRACTICE

Varicose Veins.

The sclerosing treatment of varicose veins has given rise to much talk among insurance committees and panel committees, and in the Ministry of Health. Practitioners, in the first instance, went to some trouble to learn the technique and its pitfalls. They used it in all suitable cases, whether private or panel, and the question arose whether this treatment came within the scope of ordinary panel practice. Certain practitioners claimed a fee and forwarded the appropriate form (GP 45) to their insurance committee. Under the regulations the committee has to seek the advice of the local medical committee—which usually has the same personnel as the local panel committee—on these forms. Generally speaking, local medical committees were agreed that the injection treatment was a new responsibility requiring experience, and such that a medical man of ordinary skill and standing, who trained quite efficiently possibly some years ago, could not reasonably be expected to undertake; therefore those who do undertake it, having proved their ability to do so, should be allowed a fee for their services. Insurance committees usually accept the views of the local medical committees, but here a difference of opinion arose. It was said: "This is a very simple operation. House surgeons at the hospitals, and even dressers, are doing it daily, and why therefore should the panel practitioner charge a fee for this triviality?" While it is quite true that house surgeons perform this simple operation, the responsibility is the hospital's for which he is working; moreover, he is working under instructions of a senior surgeon, and it is thought to be entirely another matter to expect the practitioner to undertake this work on his own responsibility when he may not have had the opportunity of even seeing it done.

When local medical committees and insurance committees differ, an appeal goes to the Ministry of Health, which thereupon appoints referees—a barrister and two practitioners. A decision was given by referees in a Manchester case in 1929, when it was held that this treatment is within the range of service. The matter came before the Insurance Acts Committee, and it was decided not to recognise the Manchester decision as case law, but as affecting that case only. Since that time patients have been charged for treatment regularly. Forms GP 45 have been filled in and forwarded to insurance committees, some of whom have passed them as outside the scope, while others—notably those of London, Leicester, and Kent—have refused to agree with their local medical committees. No further referees were appointed to hear these cases, and for over two years the cases accumulated. The Ministry then asked the local medical committees to accept as binding the decision of referees they would appoint to try a few simple non-complicated cases. Kent and Leicester agreed to this course, and after the hearing the decision was again that the treatment comes within the scope of the Act. With the decision came the suggestion that all old cases outstanding for decision should be treated as outside the scope, but that after the date of the decision new cases were to be inside the scope. The London local medical committee, however, would not agree to this; they are against the principle of case law, holding that each case should be dealt with on its merits, and they still pass on each GP 45 form for varicose vein injections to the insurance committee as a case outside the range of service.

The Ministry have now issued a report, dated April 26th, by the same referees who reported on Leicester and Kent in July, 1931, on some 12 cases in the London area; and, as was to be expected, they find all the cases come within the scope of the Act. They quote as confirming the correctness of this view that the Manchester referees in 1929 and those in Scotland and Northern Ireland have reached similar conclusions.

If the Insurance Acts Committee decide to accept this report as binding case law it will mean that further duties are imposed upon the panel practitioner, and this will have to be borne in mind when the next capitation fee is considered. The aim of the authorities has always been to expect panel practitioners to give the same standard of treatment to panel and private patients of the same class. Private patients willingly pay special fees for this sort of work, and the effect of this decision will probably be that many practitioners will advise their panel patients to go to hospital for this treatment—as they would if they were allowed to charge but the patient could not afford the fee. Thus it seems likely to discourage individual enterprise and increase hospital congestion.

Practitioner and King's College Hospital Scheme

The mutual benefit association, now being promoted by King's College Hospital, is somewhat similar to the British Provident Association, but not part of it. Practitioners living in the area of London served by this hospital are disturbed by the particulars of its rules and by the way the scheme has been advertised. Hospitals were, it is felt, not intended to enter into direct competition with practitioners. They were started for the treatment gratuitously of patients unable to pay their own medical man but have gradually encroached on the practitioners domain amongst artisans and better-class working people, the work however of the consultant surgeon or physician remaining gratuitous. In the new scheme this consultant class appears to gain financially at the expense of the practitioners. No income limit is placed on membership. A patient with (say) £1500 a year, and suffering from some simple medical or surgical ailment, will be able to say in effect: I will have 21 days in King's and be treated at reduced fees by a member of the staff, because I pay £1 1s. a year to that hospital. His own doctor cannot prevent him and might not even be asked about it.

A deputation of local medical men, after interviewing recently some of the committee of management cured an addition to the rules to run as follows: "10. ubscribers are normally admitted by arrangement ith the subscriber's usual medical adviser," and a ractitioner is also to be placed on the committee f management as consultative member. "The heme is however still regarded as unsatisfactory," correspondent writes, "and as the scheme is dvertised and the consultant staff benefit financially hrough its advertisement, the matter may come nder the jurisdiction of the General Medical Council. his point will, of course, be considered by those members of the staff who propose to work for reduced ees for any subscriber to the scheme, no matter hat income he may have. If not vetoed in this way ractitioners might decide to cross off their lists of pecialist consultants those members of the staff who propose to work the scheme, and who, by so doing, are in effect becoming glorified general practitioners nder the aegis of the Mutual Benefit Association. There is another point. If the scheme became really popular the hospital would be unable to provide beds for subscribers in sufficient numbers when required, and unlike the insurance service there would be no Government regulations to see that the hospital authority carried out its obligations."

Panel Committee Matters.—Psychotherapy.

At a meeting of the Panel Committee for London on Tuesday last, Dr. Cardale reported that the Insurance Acts Committee, amongst other important business, had been considering the question of anæsthetic service under the Act. London had suggested that anæsthetics should be treated as general service, not subject to special fees, and that, until this was agreed to, the local distribution scheme should be amended to 1s. for each anæsthetic. Proposals from some areas were that partners and assistants should not be recognised for special anæsthetic fees and in others it was suggested that no fees should be paid in cottage hospitals with an open staff. It was eventually decided by rather a narrow majority that special fees for anæsthetics should be abolished. The matter will have to come before the next panel conference for confirmation.

The audited accounts for the year ended 31st Dec., 1931, showed costs of just over £4300 for the year, an increase of some £800 on 1930, mainly due to the appointment of an organising and assistant medical secretary. "We are of opinion," the auditors state, "that the expenditure involved is amply justified in view of the closer relationship which has been established between the committee and its constituents through the activities of this member of the staff."

The pharmacy subcommittee heard an appeal by a practitioner under Article 4 (1) of the medical benefit regulations against the decision of the insurance committee that 11 prescriptions for soap (one tablet) do not form part of medical benefit. It appeared that castile soap was required for enemata after an operation for colostomy. The committee, while deprecating the indefinite method of prescribing, came to the conclusion that in this case, by reason of the fact that soap had a definite therapeutic value when administered as an enema, it did form part of medical benefit.

There was some discussion about the fees charged by certain specialists (£36 15s.) for giving evidence on the subject of varicose vein injections before the Ministry referees. It was decided to pay these fees without comment, but the question of cost in such cases for the future was referred to a subcommittee, who will report on what is thought to be the proper procedure.

Considerable time was taken in considering a claim under the special form G.P. 45 for permission to charge an insured person for treatment by psychotherapy for (1) violent pains in the throat (2) anxiety neurosis. Several members of the committee deprecated these claims by a general practitioner, although in this case he satisfied the regulations as to his ability to perform this service. It would, they thought, open the door to grave abuse. Most general practitioners of any standing or capability treated their panel cases by suggestion as well as by other activities without charge, and if these cases were passed for payment as being outside the scope of the Act—they were the first that had ever been applied for in London—every patient who imagined he had some neurotic condition ("such as feeling faint at the thought of work") would be treated by his panel doctor, after attending a few lectures at some clinic, by psythotherapy. On the other side it was pointed out that psychotherapy was a highly skilled modern form of treatment and that the committee should not put obstacles in the way of progress. If this item was not passed for payment, as its opponents wished, it was part of the general practitioner service: but the opposition had said it was humbug and they could not have it both ways. Eventually by a fairly large majority these services were passed as being outside the scope of the Act.

Out-patients.

A committee of King Edward's Hospital Fund for London is considering the position of out-patients at the London hospitals. It was reported to the London Panel Committee, at its meeting in April, that the impression gained by a member who had met this investigating committee was that it was thought that hospitals were doing too much work for panel practitioners in out-patient departments. The main suggestion of this investigating committee as to why so many insured patients attend an out-patient department is:—

1. The treatment given by insurance doctors may not be successful.
2. The patient has a difficulty in changing his doctor whom he may dislike.
3. His doctor may not be available when wanted.
4. His doctor is often so busy that he cannot attend his patients.

The London Panel Committee, after considering the points raised, decided to set up a section to go into the whole matter, and to ask the investigating committee to receive a deputation which would be able to rebut statements derogatory to the panel service. This section has not yet reported. There may be practitioners who delight to send a case to hospital, but they are in a minority. Most insurance practitioners wish to obtain a second opinion on some difficult point when they send a case to the out-patient department; their trouble is that the hospitals are then apt to keep the case, supply the medicine they think fit, and tell the patient to come up in fourteen days time, with the result that the insurance practitioner loses sight and interest. It is admitted, of course, that some treatments and investigations can only be done by or in a hospital, but when that is carried out and finished, the case should be returned with a report to the practitioner sending it up in the first instance. Clerical work is a practical difficulty in this scheme, for it is quite hard enough work to take an afternoon at out-patients without having to write letters on each at the end of it; but it is felt that this difficulty could be overcome by suitable organisation, with benefit to surgeon or physician, out-patient department, insurance doctor, and last but not least to the patient himself.

CORRESPONDENCE

A CONFERENCE ON RADIUM.

To the Editor of THE LANCET.

SIR,—As a member of the conference held on March 4th, at the College of Physicians to consider the question of the radium bomb, I feel that certain passages in the report of that conference which was sent to you and appears in your present issue are likely to lead to misunderstanding.

In a memorandum placed before the conference it was suggested that we, as a country, are far behind the continent both in the equipment of our institutions and in the skill of our personnel. I was fortunately able from my first-hand knowledge of the work which is being done both in this country and abroad to show that this was not the case, and I understood that I had succeeded in convincing the other members of the conference. In the necessarily brief report of the conference this does not, however, appear.

We were, however, all agreed that workers in this field have not so far been able to obtain the facilities accorded in continental countries, where the resources of the State are more directly available for the service of medicine. It will be generally agreed that a fully equipped radium institute, on a really adequate scale, in the centre of London, and supported by the laboratories, physical and pathological, and the X ray equipment which are common practice on the continent, would be of great value and would enable us to coördinate and to show to better advantage the admirable work which is already being done by individuals. I am, Sir, yours faithfully,

Harley-street, W., May 21st, 1932. H. S. SOUTTAR.

REDUCTION OF BENEFITS OF INSURED WOMEN.

To the Editor of THE LANCET.

SIR,—I was surprised that Dr. Mabel Ramsay should approach the question of the sickness of insured women from the point of view that the present insurance scheme must be accepted as it stands, and without considering whether some reorganisation of the scheme is possible so as to go further in the direction of pooling the resources for the benefit of all.

State insurance involves pooling resources for the benefit of all, and therefore any legislation which reduces the benefits payable to one section of the insured population because of the high level of claims arising from that section is contrary to its basic principle. This principle has been applied in national unemployment insurance in the interests of men, where a considerable proportion of the sums paid in by and on behalf of women are used to subsidise the men's benefits. Women have always had a lower percentage of unemployment than men. For example, in 1922, 14 per cent. of the male insured population were drawing benefit and only 7 per cent. of the women. In January, 1932, 25 per cent. of the men were drawing benefit and only 15 per cent. of the women. At no stage in the intervening ten years did the claims of the women reach the level of the claims of the men. No suggestion has been put forward at any stage that the benefits payable to men under the Unemployment Insurance Acts should be related to the percentage of claims received. It would be most unjust that this principle of pooling resources should be applied when it is in the interests of men but that it should not be applied when it is to be in the interests of women.

Assuming for the moment that it is reasonable to depart from this principle, I cannot accept the suggestion that it is women alone who should be the victims. Women are not the only section of the insured population who constitute a special burden on the funds. The miners, who are a large proportion of the male insured population, have even higher sickness and disablement claims, as the following figures, taken from the report of the Government Actuary on the third valuation of approved societies (pp. 29 and 30), show:—

General Level of Claims.

	Men.	Women.	Miners.
Sickness	92%	104%	138%
Disablement	*90%*	*138%*	*151%*

Welsh insured persons, as a whole, also are a heavy charge on the fund. *I am not suggesting that the* benefits of miners or Welshmen should be reduced. The cases are cited to illustrate the point that women are not the only expensive section of the population and to strengthen the contention that differentiation is contrary to the principle of State insurance. Women should not be penalised any more than miners or Welshmen.

The report of the Government Actuary declares that the predominant feature of the third valuation is "the magnitude of the aggregate surplus and the substantial additional benefits enuring to a large proportion of the population." £20,000,000 has been released for the payment of additional benefits, and this is to be shared among 88 per cent. of the men insured and 38 per cent. of the insured women. That is to say, the scheme on its present contributions is going to pay additional benefits to a large majority of the insured population. Since this is so, there ought to be some readjustment of the distribution of the sum available, in order to prevent the reduction of the present statutory benefits payable to insured women. It is most inappropriate to suggest where the scheme has such surpluses that the women are to be victimised.

The majority report of the Royal Commission on National Health Insurance recommended a partial pooling of future surpluses in the following words (p. 120):

> "These considerations . . . would incline us to view with favour the introduction of a measure of partial equalisation of benefits so limited in its operation as to preserve the incentives to sound and economical administration . . . but at the same time going considerably beyond the restricted scheme of pooling which was introduced, so far as the societies actually in deficiency are concerned, by the establishment of the central fund."

Besides, there is nothing to prevent the extension of the machinery of the central fund which exists to help societies which have deficiencies. An increased levy on every insured person for the benefit of this fund, with any necessary additional powers to those who administer it, might afford a possible method of dealing with the difficulty. Once the principle is accepted, as I submit it ought to be, that the pooling of risks should be a pooling which does not exclude insured women, it is not beyond the power of the Government Actuary to devise a method of giving effect to the above suggestions, or otherwise to reorganise the finances of the scheme without sacrificing the women contributors.

It has to be remembered that already existing gislation is such as to contribute to the specially igh rates of sickness among women. Poverty is erhaps the greatest cause of sickness, and the overty of women is encouraged by their low wages. hen low wages are encouraged by the trade boards hich fix by law minimum rates of wages for women enerally a little more than half those fixed for men. hen low wages are also encouraged by the practice f the Government and by many local authorities f depriving women of their work when they marry. The lower sickness and unemployment benefits ayable to women are a further cause of her greater ickness. When the sickness of women is encouraged n so many ways by present legislation, it is surely most unjust that proposals should be adopted thus urther depressing the health of women.

I am, Sir, yours faithfully,

Harley-street, W., May 24th, 1932. JANE WALKER.

NEMBUTAL AND CHLORAL IN CHILDBIRTH.

To the Editor of THE LANCET.

SIR,—We are writing to confirm the good results obtained by the use of nembutal and chloral in childbirth by Drs. O'Sullivan and Craner, as reported in their excellent paper published in THE LANCET of Jan. 16th. We are in agreement with their conclusions, and think that owing to the infrequency of troublesome restlessness when these drugs are used as compared with Van Hoosen's intensive hyoscine treatment[1] [2] or Brammer's pernocton method[3] it is the most reliable means for obtaining complete amnesia in labour at present available to the practitioner who cannot spend many hours continuously with his patient. The other two methods mentioned more constantly produce a perfect twilight sleep, but need much more careful watching.

The following is a brief record of the first 59 cases treated by us at the Leeds Maternity Hospital. We are indebted to the three senior members of the honorary staff for allowing us to use the method on their patients.

Complete amnesia. 23 cases (39 per cent.).

	interval between start of treatment and birth
Shortest	45 mins.
Longest	9¼ hours.
Average	3 hours 21 mins.

Terminal chloroform was given, for about 10 minutes as a rule, in 19 of these cases.

Fair results. 22 cases (37 per cent.).

	interval between start of treatment and birth
Shortest	25 mins.
Longest	15 hours.
Average	4¾ „

These patients had partial amnesia but remembered birth or induction of anæsthesia. The average interval between starting treatment and birth is high because four of the cases lasted over eight hours: in each of these four cases one or more of the repeat doses was not given at the right time or was omitted. Terminal chloroform was given in 14 of these cases.

Poor results. 14 cases (24 per cent.).

	interval between start of treatment and birth
Shortest	30 mins.
Longest	3¾ hours.
Average	1 hour 56 mins.

These patients obtained little or no relief. Terminal chloroform was given in 10 of the cases.

Our results have improved, no doubt as a result of practice, and are likely to improve further. Eight of the last 13 patients in this series had complete amnesia—i.e., 62 per cent. as compared with 39 per cent. in the whole series. Three main causes of the unsatisfactory results in the fair and poor cases stand out:—

(1) In five cases treatment was started within 45 minutes of delivery. We think that this is about the minimum time for the development of amnesia.

(2) In nine cases the first repeat dose or a subsequent one was omitted. It is difficult to impress on nurses the importance of giving repeat doses when due, even when birth appears to be imminent.

(3) In 12 cases the terminal chloroform was omitted. We feel that the general anæsthetic is of great help in securing a perfect result, especially in the shorter cases.

It is important not to start treatment until pains are regular and strong. Gauss's rule of waiting till pains recur every five minutes and last 20 seconds is sound.

All the babies were born in good condition. The forceps was only used in one case (there were 43 primiparæ). The method of giving chloral in sweet lemonade advised by O'Sullivan and Craner is very satisfactory. Only three patients vomited after it. Fifteen of the patients had somewhat excessive loss, and received injections of ergot and pituitary extract. Only one patient gave rise to any anxiety, and she recovered after receiving intravenous gum saline. The rule in the hospital is that sisters give ergot and pituitary extract at their discretion: it is certainly given unnecessarily on occasion: the house surgeon is only called if the patient's general condition is affected.

It is to be hoped that this method will be given an extended trial in general practice. It is, as its authors claim, safe and easily carried out, and they deserve congratulation for having evolved it and brought it to the notice of the profession.

We are, Sir, yours faithfully,

ANDREW M. CLAYE,
Leeds, May 21st, 1932. DAVID W. CURRIE.

A NEW PITUITARY SYNDROME.

To the Editor of THE LANCET.

SIR,—I have read with interest your leading article (p. 1102) under this heading. The cases seem to coincide with those described in 1921 by Achard and Thiers under the title of the Diabetes of Bearded Women (*Bull. Acad. Med.*, lxxvi., p. 53), and of which I have reported instances in *American Medicine* for 1928 and in the *St. Bartholomew's Hospital Reports* for 1930 (lxiii., p. 53). But the condition also occurs in young men, though it is less likely to be recognised as the overgrowth of hair is not so abnormal. In one of my male cases the overgrowth of the adrenal cortex was clearly seen at operation, and also in one of the female cases. But I should agree that the basophilic adenoma in the pituitary is the primary lesion. I believe that Dr. Parkes Weber's case was the first in which the basophilic character of the adenoma was described.

I am, Sir, yours faithfully,

W. LANGDON BROWN.

Cavendish-square, W., May 20th, 1932.

To the Editor of THE LANCET.

SIR,—Your leading article last week prompts us to point out that, purely on the syndrome which Cushing has elaborated from an analysis of the 12 cases which he collected from the literature since 1912, we have been enabled to recognise another example of this disorder.

---

[1] Jennings, D. R.: Brit. Med. Jour., 1929, ii., 801.

[2] Claye, A. M.: Ibid., 1931, ii., 12.

[3] Brammer, H.: Schmerz, Narkose, Anæsthesie, 1931, iii., 399.

The patient, whose clinical history we have discussed in detail in a paper to be published in the forthcoming issue of the *Guy's Hospital Reports*, died in February, 1931, without a diagnosis having been made either during life or as the result of the autopsy. On reading Cushing's paper (*Bulletin*, Johns Hopkins Hospital, March, 1932), our attention was recalled to this case, and we were fortunate enough, owing to the kindness of Prof. R. Donaldson, to gain access to the autopsy material. On cutting sections of the pituitary we found a basophil adenoma, about the size of a pin's head, lying in the front of the anterior lobe. This tumour was too small to deform the pituitary or to produce pressure symptoms or X ray evidence of pituitary enlargement.

In all essential details this case so exactly corresponds with the symptom-complex described by Cushing, that we have entitled our account of it, which is now in the press, "A Case of Cushing's Syndrome." Dr. Parkes Weber, who originally recorded one of the 12 cases referred to by Cushing has also suggested, in the last issue of the *British Medical Journal*, that "Cushing's syndrome" would be a convenient label for the disorder.

We are particularly interested in your comment on the apparently contradictory symptoms of sexual hypo-function in connexion with this disorder. To the basophil granular cell the function of secretion of the sex-maturing hormone, the Prolan A and B of Zondek, has been ascribed. On the analogy of acromegaly as a manifestation of an adenoma of the acidophil cells, one might expect increased activity of the sexual organs to be a prominent feature of the basophilic adenoma. Investigations of various pituitary rumours have been made by one of us. On the principle of the Aschheim-Zondek reaction for pregnancy, urine obtained from cases of pituitary disease has been injected into test animals, and luteinisation of the ovary has been caused by the urine of every case of acromegaly examined by this method. No such reaction has been obtained with urine from patients with other pituitary disorders, which include cases of Fröhlich's syndrome as well as pituitary tumours producing mainly pressure effects. Only one case of pituitary basophilism has been examined in this way, a case under the care of Cushing himself, and it gave a negative Aschheim-Zondek reaction. Sexual disturbances are prominent in acromegaly, and increased sexual activity is frequently one of the first symptoms, though later impotence and amenorrhœa are the rule.

These findings are suggestive of the connexion of the acidophil rather than the basophil cell with the regulation of the sexual rhythm, and to some extent, serve to indicate the value of the further recognition and investigation of Cushing's syndrome as a possible means of determining the function of the basophil cells of the anterior lobe of the pituitary.

We are, Sir, yours faithfully,
P. M. F. BISHOP,
H. G. CLOSE.

Guy's Hospital, S.E., May 23rd, 1932.

NIETZSCHE'S PHILOSOPHY.

To the Editor of THE LANCET.

SIR,—I beg to thank you for your kind comment upon my new pocket edition of Nietzsche's "Thus Spake Zarathustra" (Allen and Unwin), and I hope, with your reviewer, that "it may find many readers in the medical profession." Nietzsche indeed relied for his recognition upon our profession and its sober art, for he had an inkling that his own confrère would look askance for a long time still upon a thinker who, instead of an imaginary "soul," again drew men's attention back to their bodies. "Thus Spake Zarathustra" contains a special chapter against those "uplifting" philosophers who wish to lead mankind into celestial heights and away from this earth and their bodies. It bears the title "The Despisers of the Body," and it begins as follows: "To the despisers of the body will I speak my word. I wish them neither to learn afresh, nor teach anew, but only to bid farewell to their own bodies—and thus be dumb."

I am, Sir, yours faithfully,
OSCAR LEVY, M.D. (Freiburg), L.R.C.P. (Lond.), M.R.C.S. (Eng.).
Editor of the authorised English translation of Nietzsche's works.

Wiesbaden, May 23rd, 1932.

CHEAPNESS AT ALL EVENTS.

To the Editor of THE LANCET.

SIR,—"Panic in the district." So runs the newspaper headline concerning an appointment of "matron-superintendent" to a mental defective colony shortly to be started.

The position is an interesting one as illustrating the relationship of local authorities to the Board of Control. The colony in question is to be run by a joint committee of two county and two borough councils. It is to cater at first for 200 patients; adolescents and adults of both sexes are to be accommodated. The buildings are to be an adapted mansion and outbuildings, and a large estate has to be worked and organised.

For the supreme control of this colony the administrative officer, a "matron-superintendent," is offered a salary of £160 a year (resident). The Board of Control is quoted as being entirely satisfied that the post can be adequately filled by such a person, *at this remuneration*. The local committee is therefore content. It is apparently nobody's business to assess the merits of the appointment to consider what qualities of personality and leadership, what psychological and cultural background can be obtained at such a rate of pay. Medical care and assessment are apparently secondary considerations, though the indefinite boundary between lunacy and deficiency is well known and is certain to give rise to difficulties.

The main consideration at every point is "cheapness." No one wants to spend on defectives: when driven to do so let the ultimate minimum be sought. Personnel?—the cheapest. Estate management and equipment?—the least possible. Research?—none.

"Panic in the district" is perhaps an exaggeration, but if it were fact it might be better than the apathy which allows public institutions to be run with so little imagination.

I am, Sir, yours faithfully,
A MEDICAL OBSERVER.

May 18th, 1932.

GEORGE EDWIN LOWE HOSPITAL.—An extension to this hospital at Sutton Coldfield, which forms part of the Princess Alice Orphanage (the Birmingham and Midland branch of the National Children's Home), was opened recently by Sir Arthur Steel-Maitland, M.P. The extension, which is the gift of Mrs. Lowe, takes the form of a sick room with an outside staircase providing access for infectious cases without traversing the main hospital building.

OBITUARY

JOHN CLOUGH THRESH, M.D. Vict., D.Sc. Lond., D.P.H., F.I.C.,

LATE M.O.H. FOR THE COUNTY OF ESSEX.

WE regret to announce the death of Dr. Thresh, the well-known sanitarian, which occurred at Chelmsford on May 23rd at the age of 82.

John Clough Thresh, the son of James Thresh, an engineer who worked in Peru, was born at Wakefield in 1850, and was educated privately and at Owens College, Manchester. He elected to make pharmaceutical chemistry his special subject, and graduated at the University of London in science, obtaining the D.Sc. in 1884. He later resolved on the study of medicine, and in 1889 took the M.B., Ch.B. Vict., proceeding to the M.D. in 1896, when he was awarded the gold medal for a thesis. He had already, in 1892, obtained the D.P.H. Camb. He remained for a period in Manchester where he was engaged in analytical work, at which time also he wrote a short text-book, entitled "Physics, Experimental and Mathematical," and investigated the claims of Buxton as a health resort by analysing the thermal springs. He also made an instructive report on excessive mortality in certain of the Manchester districts.

DR. THRESH.

Photograph by Elliott & Fry.

With his varied training and experience, and exceptional knowledge of chemistry, he was attracted to the public health service, became an early pioneer in establishing the importance of environmental hygiene, and attracted considerable attention by the thoroughness of his work. He was appointed the first county medical officer of health for Essex, and occupied that position for 22 years, when he became consulting medical officer, a post which he held until some nine years ago, when ill-health compelled him to resign. His work during his long period of office was of the first order, far-ranging, fruitful, and suggestive. His reports discussed such problems as excessive infantile mortality, the value of isolation hospitals, the housing of the agricultural labourer and working-classes, the preservation of and preservatives in food, and especially water and water-supplies. As a thesis for the degree of M.D. he had submitted an essay on this last subject, for which the University awarded him a special gold medal, and the dissertation proved to be the skeleton of a volume which he published in 1896. In this he summarised accepted knowledge in reference to water-supply, with special reference to drinking water. The chemical and bacteriological examination of drinking water was at that period already elaborate, but it was clear that in some cases the results were of questionable value, and public opinion on that matter was strengthened by facts which came out now and again during epidemics of typhoid fever. Water under chemical and bacteriological analysis could not be properly tested and found innocuous, while it was apparently the active agent in the spread of disease. Thresh's book supplied an interpretation of water analyses which was recognised as being logical, and proved to be of high practical value. He also carried out researches into the general purification of water and the effect of water upon health, the reactions of water to lead and copper, and was the inventor of various sterilisation processes; indeed, as a result of his experiments, the excess lime process of water treatment was recently sanctioned by Parliament as an efficient method in the purification of river sources.

His annual report on the Chelmsford and Maldon rural districts, of which he was medical officer at the same time as being the county M.O.H., formed excellent sanitary surveys of an English rural county, and a group of them (1900–1905) were published in book form. Here were discussed building laws in reference to cottage property, housing for the working-classes, prevalence of diphtheria and scarlet fever especially among children, the origin of isolated outbreaks of these scourges, and the cancer mortality of the population. In respect of the last inquiry the conclusions negatived a great many views then popular as to the ætiology, a low mortality from cancer being found to exist under the most diverse physical and sanitary conditions. In 1904 he expanded and added to his previous book on water-supplies and published a work, entitled the Examination of Waters and Water-supplies. This was written in the light of all the recent investigations for the isolation and recognition of the flora of sewage; it considerably modified the conclusions that had been drawn from many bacteriological examinations, for these, it was seen, might be as fallacious as those derived from chemical analysis. He urged further, the importance of making a careful inspection of the source of supply by those actually engaged in the examinations, and made important suggestions for the protection and control of water-supplies out of the results of a long experience. This book stamped Thresh as being one of our first authorities on the whole subject.

Thresh held many important public appointments and discharged many responsibilities. He was at different times honorary secretary to the British Pharmaceutical Congress, examiner in chemistry to the Pharmaceutical Society, lecturer in public health at the London Hospital, and examiner in State medicine at the University of London. He began his sanitary work when the organised study of public health in actual relation to the conditions of rural life was in its infancy, and during his long career many medical officers of health and workers in preventive medicine have benefited by his labours and his actual teaching. His precision of mind and the great skill, industry, and resource with which he faced any problem could not fail to impress deeply his assistants and pupils, and formed a valuable example for their work. These qualities of clear thought and capacity for research, in addition to knowledge and experience, made him in great demand as an expert witness in connexion, principally, with questions relating to water-supply, and his words were always listened to with close attention by any

Parliamentary committee or court before which he appeared. All who have noted the changes in public health administration and in the prevention of disease which have occurred in the last 50 years should deplore the death of one of the great pioneers. For many years he was a constant editorial contributor to THE LANCET, and during his period of active connexion with the paper we derived varied benefits from his counsel.

Dr. Thresh married in 1872, and his wife who predeceased him, was his constant help-mate throughout his long and strenuous public career. His home life was quiet and unostentatious, and only those who knew him well could fully realise his kindly nature or know of his many generous deeds. He was a reserved man, but his intimates knew his warmth of heart. He leaves three daughters to whom all sympathy will go out.

Sir Alexander Houston writes: "There is no country that will not mourn the death of Dr. Thresh, for his disciples and admirers were scattered over the habitable globe. He was a great administrator and a splendid teacher, and his knowledge and its versatility, combined with his patience and capacity for hard work, rendered him one of the most striking figures in the public health service. He will be chiefly remembered for his magnificent work on water-supply, where his influence was profound, embracing every aspect—epidemiological, chemical, bacteriological, and physical. He was equipped on all points with experience personally gained. Much of his work was original, all of it was characterised by meticulous accuracy and attention to detail. Although his fetish was pure water, he was extremely tolerant towards new ideas, and was always in the van in connexion with the trial of any proposed novel departures from old-established custom. The splendid new water-supply to Southend, treated by the excess lime method of purification, is a notable example of his prowess.

"Personally I shall miss him greatly, a friend of 40 years' standing, and his other disciples all over the world will mourn with me the loss of so distinguished a scientist, so estimable a man, and so irreplacable a figure in the world of water-supply."

Dr. JOHN JAMES BOYD, who died at Pretoria on May 3rd, at the age of 63, was a native of Mains, Dundee, and graduated in medicine at Glasgow in 1892. He became assistant medical officer of health for Southampton, and later medical officer for South Shields. Then in 1904 he left this country to take up the appointment of M.O.H. for Pretoria, capital of the Union of South Africa, where he was virtually the creator of the health department. In 1929, having reached the age limit, he left Pretoria for Salisbury, in Southern Rhodesia, where he held the same appointment; but last November he was obliged to relinquish it because of ill-health. During the war Dr. Boyd served in France with the British Expeditionary Force.

Dr. VALENTINE PRESTON PAXON died on May 7th in his twenty-eight year. He was serving as house surgeon at the Queen's Hospital for Children, when he contracted diphtheria, to which he succumbed after just over a week's illness. Educated at Eastbourne College, Paxon began his medical training at Caius College, Cambridge, and went on to St. Thomas's Hospital, qualifying in 1930. Afterwards he was house surgeon at the Royal Berkshire Hospital, Reading, where he gained affection and respect, and where he showed evidence of unusual aptitude for surgery. He took up his appointment at the Queen's Hospital for Children in February, and here again he had won the trust and affection of those with whom he worked.

Dr. WILLIAM HOWARD BLACKBURN, who died on May 11th, at the age of 39, had been medical officer of health for Lowestoft for the past five years. Born at Wallasey, he took the Natural Sciences Tripos at Cambridge in 1914, and qualified in 1916. After serving with a temporary commission in the Navy he returned to graduate in medicine at Cambridge, and obtained the D.P.H. in 1922. He then entered the public health service, in which he seemed likely to go far. A colleague writes of him that he was a man of exceptional merit and personality. "He had an enormous capacity for work, and it was this intense love for his work which unfortunately laid him low, in that his illness commenced with influenza when working at high pressure during an outbreak of diphtheria at Lowestoft. Despite his illness, however, he would not give up work and was in harness until practically the last, earning from the mayor of Lowestoft the tribute that 'it was simply the way he gave himself up to his duty that was the cause of his death.' Personally he was most lovable, ever ready to give a helping hand, and ever cheerful. Everybody who knew him regrets not only the passing of a colleague of the highest type, but of a staunch friend." Dr. Blackburn had held resident appointments at both St. Bartholomew's and St. George's Hospitals. He was formerly deputy M.O.H. for St. Helens.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Capt. (retd.) A. R. Thomas to be Surg. Rear Admiral (retd.).

Surg. Comdr. H. B. Padwick is placed on the retd. list at own request with rank of Surg. Capt.

Surg. Comdr. H. W. Nicholls is placed on the retd. list with rank of Surg. Capt.

Surg. Comdr. W. C. Carson is placed on the retd. list.

The following appointments are notified:

Surg. Comdrs. A. J. Tozer to *Resource*; A. E. P. Cheesman to *Victory*, for Haslar Hospital, for course; W. J. Morris to *Frobisher*, as Fleet Medical Offr.; and R. F. Quenton to *Comus*.

Surg. Lt.-Comdr. (D.) W. E. A. Sampson to *Victory* for R.N. Barracks.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Sub-Lt. S. C. Suggit to be Surg. Lt.

Surg. Lt. (D) G. A. O. White to be Surg. Lt.-Comdr. (D).

ROYAL ARMY MEDICAL CORPS.

Maj. F. R. Coppinger to be Lt.-Col.

The undermentioned Lts. (on prob.) are confirmed in their rank: H. C. Morton, A. D. Low, and J. N. Low.

PRIZE WINNERS IN THE R.A.M.C.

The following are names of the prize winners in the Junior Class of Instruction for Officers of the Royal Army Medical Corps and Indian Medical Service at the Royal Army Medical College, at the session which terminated on April 29th last:

Lt. F. A. B. Sheppard (Melbourne University), I.M.S., Herbert Prize (Highest Aggregate) and Fayer Memorial Prize (Pathology); Lt. P. T. L. Day (Guy's Hospital), R.A.M.C., Marshall Webb Prize (T[illegible] Administration); Capt. W. Happer[illegible] I.M.S., Parkes Memorial Prize (Hygiene); Lt. J. M. [illegible] (St. Mary's Hospital), R.A.M.C., De Chaumont Prize (Hygiene); Lt. M. Sendak (St. Mary's Hospital), I.M.S., Ranald Martin Prize (Tropical Medicine); Lt. R. D. Macrae (Aberdeen University), R.A.M.C., Tulloch Memorial Prize (Pathology); Lt. R. I. Reid (Trinity College, Dublin), I.M.S., 1st Montefiore Prize (Military Surgery); Lt. W. A. N. Marrow (Middlesex Hospital), I.M.S., 2nd Montefiore Prize (Military Surgery).

MEDICAL NEWS

University of Oxford.

It is proposed that the honorary degree of D.C.L. shall be conferred on Lord Moynihan on June 1st, before he delivers the Romanes lecture. The subject of the lecture is the Advance of Medicine.

Society of Apothecaries of London.

At recent examinations the following candidates were successful:

MASTERY OF MIDWIFERY.

R. G. Bradford, W. A. Rees, and J. L. M. Wood.

Territorial Army Medical Officers' Association.

The annual meeting and dinner of this association will be held at the Dorchester Hotel on Saturday, May 28th. The meeting will be at 7.30 P.M. and the dinner at 8 P.M. All Territorial Army medical officers (active and retired) are invited to be present.

Demonstrations of Contraceptive Technique.

The Society for Constructive Birth Control and Racial Progress informs us that at 2.30 P.M. on Wednesday, June 1st, demonstrations of contraceptive technique will be given to practitioners and senior medical students. Application for tickets should be made to the hon. secretary of the Society, at 108, Whitfield-street, London, W.1.

British Health Resorts Association.

The fifth conference, for the spas of Mid-Wales, was held at Llandrindod Wells from May 20th–23rd, under the chairmanship of Sir Humphry Rolleston, the delegates being welcomed by Dr. Miller Kerr, president of the local medical society. It was, said Sir Humphry, one bright spot of the financial crisis that it had turned attention to the value of British places, products, and methods of physical treatment. Success depended on the combined action of local authorities and medical men: the latter should ascertain what kinds of patients and ailments were suitable for treatment, and how treatment could be applied to the greatest advantage. The meeting was made the occasion for the presentation of a statement (see p. 1164) in appreciation of the home spas by the medical advisory committee of the Association. In presenting this statement, Dr. Fortescue Fox suggested a survey of the medicinal waters of the country. Dr. W. Langdon Brown, in opening the discussion, said that a striking feature of twentieth century medicine had been a return to the Æsculapian cult; treatment by sunlight, fresh air, baths, the drinking of waters, and psychological exploration. The rise of scientific medicine in the nineteenth century had, curiously enough, been accompanied by a neglect of all these methods and by a concentration on the end-results of disease. Dr. E. A. Goulden (Llandrindod) discussed the rôle of water-drinking in preventive medicine. Dr. George Worthington described the uses of the saline waters of Llandrindod, sometimes in very large doses, as a method of gastro-intestinal lavage, often beneficial in chronic toxæmias due to digestive catarrh. Mr. S. Judd Lewis, D.Sc., explained the new classification of medicinal waters which had already been approved in several European countries (see THE LANCET, 1931, i., 31). He laid emphasis on the significance of elements present in minute quantities, such as iodine, manganese, copper, and boron. At the afternoon session Sir William Willcox recalled the mention of Llandrindod by Pliny; the medical value of this and of the waters at Llanwrtyd and Trefriw justified the movement for their more complete development. Dr. R. Ackerley pointed out that Llandrindod offered, for those who needed them, the two characteristics of a bracing climate—dryness and movement of air. Dr. William Byam held that in general the health resorts should be regarded as places both for cure and convalescence, not omitting the investigation of disease. Among health resorts, the spas should be the specialists, whilst coast resorts might be regarded as general practitioners. The former should not deal with all and sundry, but concentrate on the particular values of the place. Dr. J. W. Patterson (Droitwich) believed there was much wastage in the examination of cases at spas, and advocated the use of an approved questionaire in the interview with rheumatic patients. Prof. Douglas Stanley (Birmingham) pointed out that the spa practitioner had an insufficient grasp of the class of patients cured by the osteopath, which could be equally benefited at the health resorts. There should, he agreed, be a more careful estimation of the type of cases suitable for particular spas. Dr. John Murray (Llandrindod) appealed for facilities at the spas for the accommodation and treatment of industrial workers, who broke down in early adult life with rheumatic and other preventable diseases. On Sunday most of the party were entertained to luncheon by the Mayor of Aberystwith, whilst others visited the sulphuretted springs at Llanwrtyd. The programme concluded with a special performance of the Royal Mountain Ash Welsh Male Choir.

London Hospital Medical College and Dental School.

Prizes and certificates for the current year will be presented by Sir William H. Goschen, chairman of the house committee of the hospital, at 3 P.M. on Friday, June 24th, in the College Library.

Argentine Medical Students in England.

Of nine Argentine students now visiting Great Britain under the leadership of Dr. Carlos Waldorp, three are studying medicine. From June 16th they will make a tour of some of the London hospitals and medical schools, and will also visit Frimley Sanatorium and the Treloar Hospital at Alton.

The New Freemasons' Hospital.

On May 19th, with full Masonic ceremony, the Duke of Connaught, Grand Master of the Grand Lodge of English Freemasons, laid by electric contact the dedication stone of the new Freemasons' Hospital at Ravenscourt Park, Hammersmith. Since only a relatively small number of people could have been placed on the hospital site, the ceremony took place at Olympia, whence, as the Duke of Connaught laid a small duplicate, the actual stone was placed in position by electricity. The Prince of Wales, the Duke of York, Prince George, and Prince Arthur of Connaught were also present, with 8000 other Masons and 3000 ladies. The new hospital, to replace the existing building in Fulham-road, will cost £300,000 and will contain 180 beds; the present one has only 50. It will do much to meet the growing demand for accommodation for Masonic paying patients. It is expected that the new hospital, which stands in between five and six acres of grounds, will be opened in the summer of next year.

Fellowship of Medicine and Post-Graduate Medical Association.

The first of a series of four lecture-demonstrations on Wednesdays at 5 P.M. will be given on June 1st at the Royal Free Hospital by Dame Louise McIlroy. Prof. Arthur J. Hall will give the first of three lectures on Epidemic Encephalitis at 11, Chandos-street, W., at 8.30 P.M., on Thursday, June 2nd. Dr. Knyvett Gordon will give an epidiascope and laboratory demonstration on Splenic Enlargement at 10, Bedford-square, W.C., at 8.30 P.M., on Wednesday, June 1st. Forthcoming all-day courses include: medicine, surgery, and the specialties, at the Prince of Wales's Hospital, Tottenham (June 6th to 18th); gynæcology, at the Chelsea Hospital for Women (June 6th to 18th); diseases of the chest, at the Victoria Park Hospital (June 6th to 18th). A course in diseases of children will be held from June 25th to July 9th at the Children's Clinic and other hospitals, and a week-end course in diseases of the chest will be given on June 25th and 26th at the Brompton Hospital. A fortnight's course in dermatology will be held at the Blackfriars Skin Hospital from June 27th to July 9th, in the afternoons. All the above courses and lectures are open only to members of the Fellowship. The secretary's address is 1, Wimpole-street, W.1.

The Guardianship Society.

This society, whose headquarters are at Brighton, is now in its twentieth year, and continues to extend its work. Its object is the care and supervision of the mentally and physically defective and other special cases by boarding them out in families, assisting them to obtain training and employment suited to their capabilities, visiting them, and taking a friendly interest in their moral and material welfare. It having been decided to end the financial year on March 31st, instead of Sept. 30th, the report submitted at the annual meeting on April 27th covered a period of 18 months. During that period no fewer than 1038 cases were under its care, and the sum disbursed on behalf of patients amounted to £47,009. Only £2046 went in administrative expenses; the hon. secretary, Miss Grace Woodhead, who has held that post since the inception of the society, has, it was stated, "not only worked seven days a week for nothing, but has put a great deal of money into the organisation." The report emphasised the useful work which was done on two training farms in Sussex; described the activities of the clinic for nervous disorders as one of the finest branches of the work, resulting in saving by far the largest proportion of the patients from the distress of becoming certified; and announced that in addition to the three occupation centres at Brighton and one at Hove, there had been added one at Peacehaven and one at Heathfield, while, in addition, workers visited the Mental Hospital at Haywards Heath once a week and held a class among the women patients. At the conclusion of the annual meeting an address was given by Dr. J. R. Rees, deputy director of the Institute of Medical Psychology, London, on the wider aspects of mental disorders.

Parliamentary committee or court before which he appeared. All who have noted the changes in public health administration and in the prevention of disease which have occurred in the last 50 years should deplore the death of one of the great pioneers. For many years he was a constant editorial contributor to THE LANCET, and during his period of active connexion with the paper we derived varied benefits from his counsel.

Dr. Thresh married in 1872, and his wife who predeceased him, was his constant help-mate throughout his long and strenuous public career. His home life was quiet and unostentatious, and only those who knew him well could fully realise his kindly nature or know of his many generous deeds. He was a reserved man, but his intimates knew his warmth of heart. He leaves three daughters to whom all sympathy will go out.

Sir Alexander Houston writes: "There is no country that will not mourn the death of Dr. Thresh, for his disciples and admirers were scattered over the habitable globe. He was a great administrator and a splendid teacher, and his knowledge and its versatility, combined with his patience and capacity for hard work, rendered him one of the most striking figures in the public health service. He will be chiefly remembered for his magnificent work on water-supply, where his influence was profound, embracing every aspect—epidemiological, chemical, bacteriological, and physical. He was equipped on all points with experience personally gained. Much of his work was original, all of it was characterised by meticulous accuracy and attention to detail. Although his fetish was pure water, he was extremely tolerant towards new ideas, and was always in the van in connexion with the trial of any proposed novel departures from old-established custom. The splendid new water-supply to Southend, treated by the excess lime method of purification, is a notable example of his prowess.

"Personally I shall miss him greatly, a friend of 40 years' standing, and his other disciples all over the world will mourn with me the loss of so distinguished a scientist, so estimable a man, and so irreplacable a figure in the world of water-supply."

Dr. JOHN JAMES BOYD, who died at Pretoria on May 3rd, at the age of 63, was a native of Mains, Dundee, and graduated in medicine at Glasgow in 1892. He became assistant medical officer of health for Southampton, and later medical officer for South Shields. Then in 1904 he left this country to take up the appointment of M.O.H. for Pretoria, capital of the Union of South Africa, where he was virtually the creator of the health department. PRIZE WINNERS IN THE R.A.M.C.

The following are names of the prize winners in the Junior Class of Instruction for Officers of the Royal Army Medical Corps and Indian Medical Service at the Royal Army Medical College, at the session which terminated on April 29th last:

Lt. F. A. B. Sheppard (Melbourne University), I.M.S., [illegible] Prize (Highest Aggregate) and Fayer Memorial [illegible] P. T. L. Day (Guy's Hospital), [illegible] Prize (Military Medical Admini- [illegible] Happer (Edinburgh University), [illegible] Prize (Hygiene); Lt. J. M. Low [illegible] R.A.M.C., De Chaumont Prize (Hygiene); Lt. M. Sendak (St. Mary's Hospital), I.M.S., Ranald Martin Prize (Tropical Medicine); Lt. R. D. Macrae (Aberdeen University), R.A.M.C., Tulloch Memorial Prize (Pathology); Lt. R. I. Reid (Trinity College, Dublin), [illegible] Prize (Military Surgery); Lt. [illegible] I.M.S., 1st [illegible] Hospital), I.M.S., 2nd [illegible] W. A. N. [illegible] Montefiore Prize [illegible]

THURSDAY.—10 A.M. to 1 P.M., Neurological Out-patients, Fracture Demonstration. 2 to 4 P.M., Operations, Medical, Surgical, Eye, and Genito-Urinary Out-patients. 4.15 P.M. (Special lecture), Dr. Konstam: Pulmonary Tuberculosis.

FRIDAY.—10 A.M. to 1 P.M., Medical Wards, Skin Out-patients, Dental Department. 2 to 4 P.M., Operations, Medical, Surgical, and Throat Out-patients.

SATURDAY.—9 A.M. to 1 P.M., Throat, Nose, and Ear Operations, Medical Wards, Children's Medical Out-patients, Surgical Wards, Surgical Out-patients. The Lectures at 4.15 P.M. are open to all Medical Practitioners without fee.

LONDON JEWISH HOSPITAL, Stepney Green, E.

THURSDAY, June 2nd.—4.15 P.M. (Tea at 4 P.M.), Mr. H. S. Souttar: Surgical Applications of Radium.

NATIONAL HOSPITAL, Queen-square, W.C.

MONDAY, May 30th.—2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Mr. Leslie Paton: Optic Atrophy.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Martin: Parkinsonism.

WEDNESDAY, June 1st.—2 P.M., Dr. Martin: Out-patient Clinic.

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Critchley: Senile Cerebellar Syndromes.

FRIDAY.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. Walshe: Peripheral Neuritis.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

WEDNESDAY, June 1st.—4 P.M., Dr. C. E. Lakin: Demonstration of Medical Cases.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, May 31st.—3.15 P.M., Mr. R. Wade: Some Modern Changes in Anæsthesia.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, June 3rd.—4 P.M., Mr. N. Asherson: Otalgia.

ST. PETER'S HOSPITAL, Henrietta-street, Covent Garden, W.C.

WEDNESDAY, June 1st.—3 P.M., Dr. C. Dukes: Tumours of the Lower Urinary Tract.

NATIONAL CENTRE AND POST-GRADUATE SCHOOL OF RADIOTHERAPY, Riding House-street, W.

WEDNESDAY, June 1st.—4.30 P.M., Dr. Finzi: Deep Therapy.

Appointments

MOLL, H. H., M.D. Rome, M.R.C.P. Lond., has been appointed Hon. Assistant Physician to the General Infirmary at Leeds.

London County Council: WALMSLEY, N. W., M.D., Ch.B. Liverp., D.P.H., Medical Superintendent, South Western Hospital. PFISTER, Miss HILTA I. C., M.B., Ch.B. Edin., D.P.H., Assistant Medical Officer, Grade I., St. Alfege's Hospital. WILLIAMS, B., F.R.C.S. Edin., M.B., Ch.B. Edin., Assistant Medical Officer, Grade I., Hammersmith Hospital.

Certifying Surgeons under the Factory and Workshop Acts: Hicks, E. B., L.R.C.P., L.R.C.S. Ed., L.R.F.P.S. Glasg (Easingwold); MacGirr, P., M.B., B.Ch.N.U.I. (Meltham).

Vacancies

For further information refer to the advertisement columns.

Albert Dock Hospital, Connaught-road, E.—Res. M.O. At rate of £110.

All Saints' Hospital for Genito-Urinary Diseases, Austral-street, West-square, [illegible] *S.E.*—Res. H.S. At rate of £100.

B[illegible]*d Dispensary.*—Res. Surg. O. £300.

B[illegible]*onsdale Hospital.*—H.S. £175.

L[illegible] Second H.S. At rate of £140.

Benenden, Kent National Sanatorium.—Res. Asst. M.O. £300.

Birmingham City Mental Hospital.—Jun. Asst. M.O. £350.

Birmingham and Midland Eye Hospital, Church-street.—H.S. £110.

Bradford, Royal Eye and Ear Hospital.—Jun. H.S. £150.

Burnley, Victoria Hospital.—H.P. At rate of £150.

Burton, [illegible] Asst. H.P. At rate of £150.

Cancer [illegible] *S.W.*—H.S. At rate of £100.

Cardiff [illegible] Ophth. Surgeon.

Carlisle, Cumberland Infirmary.—Second H.S. £155.

Carshalton, Queen Mary's Hospital.—Res. Asst. M.O. £350.

Chesterfield and North Derbyshire Hospital.—H.S. £150.

Coventry and Warwickshire Hospital.—Res. Cas. O. £125.

Derby, Derbyshire Royal Infirmary.—H.S. for General Surgery. £150.

Doncaster Royal Infirmary.—H.S. and Cas. H.S. Each at rate of £175.

Dreadnought Hospital, Greenwich.—H.P. and H.S. Each at rate of £110.

Dundee Royal Infirmary.—Hon. Asst. Visiting M.O. for Diseases of the Skin.

Durham County Council Education Department.—Asst. Oculist. £500.

East Ham Memorial Hospital, Shrewsbury-road, E.—Res. M.O. At rate of £200.

Hornsey Borough.—Asst. M.O.H., &c. £600.

Ilford, King George Hospital.—H.S. At rate of £100.

Indian State Railways.—District M.O. Rs.650 per mensem.

Infant Hospital, Vincent-square, Westminster.—H.P. At rate of £75.

Ipswich, East Suffolk and Ipswich Hospital.—Res. M.O. £350.

Jerusalem, St. John Ophthalmic Hospital.—H.S.

Lancaster County Mental Hospital.—Asst. M.O. £500.

Liverpool, New Liverpool and Samaritan Hospital for Women, Catherine-street.—H.S. At rate of £100.

Llangwyfan, nr. Denbigh, North Wales Sanatorium.—Jun. Asst. Res. M.O. £250.

L.C.C. Mental Hospital Service.—Asst. M.O. £475.

London Hospital, E.—Asst. Surgeon to Ear, Nose, and Throat Dept.

Manchester Royal Eye Hospital.—Jun. H.S. £120.

Manchester, St. Mary's Hospital, Whitworth-street.—H.S. At rate of £50.

Miller General Hospital, Greenwich-road, S.E.—Cas. O. At rate of £150. Also H.S. and H.P. Each at rate of £100.

National Hospital, Queen-square, W.C.—Asst. Pathologist. £250.

Newcastle General Hospital.—H.S. At rate of £150.

North-Western Fever Hospital, Lawn-road, Hampstead, N.W.—H.P. At rate of £80.

Nottingham General Hospital.—Res. Cas. O. At rate of £200.

Oxford, Warneford Mental Hospital.—Second Asst. M.O.

Preston, Royal Infirmary.—Cas. O. £150.

Princess Beatrice Hospital, Richmond-road, Earl's Court, S.W.—Res. Med. Supt. At rate of £120.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Two Res. Anæsthetists. Each at rate of £100.

Royal Air Force.—Vacancies.

Royal Chest Hospital, City-road, E.C.—Med. Regs. £50.

Royal Free Hospital, Gray's Inn-road, W.C.—H.S.'s, H.P.'s, &c. All at rate of £100. H.P. to Children's Dept. Also Asst. Phys.

St. George-in-the-East Hospital, Raine-street, Wapping, E.—Res. Asst. M.O. £350.

St. John's Hospital for Diseases of the Skin, 49, Leicester-square, W.C.—In-patient Med. Reg. £50.

St. Mark's Hospital for Cancer, &c., City-road, E.C.—Res. Surg. O. At rate of £150.

St. Mary's Hospital for Women and Children, Plaistow, E.—Two Hon. Asst. Phys. Also Clin. Asst for Med. Out-Patients' Dept.

St. Stephen's Hospital, Fulham-road, S.W.—Clin. Asst. At rate of £100.

St. Thomas's Hospital, London, S.E.—Two Med. Regs. Also Physician for Skin Dept.

Salford City.—Jun. Asst. for Venereal Diseases Treatment Centre. At rate of £500.

Salford Royal Hospital.—Med. Reg. £250. Also H.P.'s and H.S.'s. Each at rate of £125.

Salisbury General Infirmary.—Two H.S.'s. Each £150.

Sheffield, Jessop Hospital for Women.—Sen. Res. O. At rate of £120.

Shrewsbury, Royal Salop Infirmary.—Cas. O. and Res. Anæsthetist. At rate of £160.

Southampton, Royal South Hants and Southampton Hospital.—Radium Officer. £600.

Stockport Infirmary.—Jun. H.S. £150.

Truro, Royal Cornwall Hospital.—H.S. £170.

Victoria Hospital for Children, Tite-street, Chelsea, S.W.—Surg. to Ear, Nose, and Throat Dept.

Wales, University of.—Lord Merthyr Research Scholarship, £200, and Mrs. John Nixon Research Scholarship and Ewen Maclean Research Scholarship. Each £150.

Warrington Infirmary and Dispensary.—Jun. H.S. £175.

Warwick, Hertford Hill, King Edward VII. Memorial Sanatorium.—Jun. M.O. At rate of £200.

West London Hospital, Hammersmith-road. W.—H.P. and H.S. Each at rate of £100.

Westminster Hospital Annexe, 66, Fitzjohn's-avenue, Hampstead. Res. M.O. £200.

Weston-super-Mare General Hospital.—Res. H.S. £150.

Willesden General Hospital, N.W.—Clin. Assts. for Out-patient Department.

Wrexham and East Denbighshire War Memorial Hospital.—Two Res. H.S.'s. Each at rate of £150.

Births, Marriages, and Deaths

MARRIAGES.

SMITH—SOWTER.—On May 18th, at St. Patrick's Church, Soho, Leslie Muir Smith, M.R.C.S., L.R.C.P., to Kathleen Adela Sowter, daughter of Mr. John Sowter, Becmead, Eastbourne.

STALLARD—PAGE.—On May 21st, at St. Bartholomew's the Great, London, by the bride's father, H. Bristow Stallard, F.R.C.S., to Gwynneth Constance, daughter of Canon and Mrs. F. G. T. Page, of Warwick.

DEATHS.

BENSON.—On May 22nd, Alfred Benson, M.A., M.B., B.Ch. Oxf., of Maida Vale, W.

COX.—On May 20th, at a nursing home, Robert Cox, B.A., M.B., B.Ch., B.A.O., of Calton-avenue, Dulwich, S.E.

FOWLER.—On May 15th, at Cotford House, Thornton Heath, Charles Owen Fowler, M.D., M.R.C.S., J.P., aged 72.

HARRIS.—On May 17th, Percy Reeves Traer Harris, M.R.C.S., F.S.A., of York House, Kensington, aged 70 years.

OWST.—On May 17th, at a nursing home, Arthur Robert Owst, F.R.C.S. Edin., of Puckpool, Ilkley.

SAUNDERS.—On May 18th, at the Beeches, Wales, Sheffield, Matthew Browne Saunders, M.B.

THRESH.—On May 23rd, at Spergula, Chelmsford, John Clough Thresh, M.D., D.Sc., late medical officer of health to the County of Essex, in his 82nd year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

MR. DIGBY COTES-PREEDY, K.C., has been appointed Recorder of Oxford. He qualified as L.S.A. Lond. in 1903, and was house physician at St. George's Hospital before being called to the Bar in 1904.

THE Anglo-French Drug Co., Ltd., announce that on and after June 1st the address of the firm will be 11 and 12, Guilford-street, W.C.1. Telephone: Holborn 6011.

The International Trachoma Prize.

It is announced that this prize, offered by the Royal Hungarian Minister of Public Welfare, is to be divided equally between Dr. Ugo Lumbroso (Tunis) and Dr. J. Taboriski (Palestine). Honourable mention is given to Dr. Cattaneo (Sassari), Dr. P. Olitsky (New York), Drs. Rötth and Kanyó (Budapest), and Dr. C. Trapezontzewa (Moscow). The prize is of the value of 2000 Swiss francs, and the jury of award consist of Mr. A. F. MacCallan (London), Dr. Victor Morax (Paris), Dr. Luigi Maggiore (Bari), Prof. Carl Prausnitz (Breslau), and Prof. Emile de Grósz (Budapest).

Southport Infirmary.

On May 6th Sir Hilton Young, the Minister of Health, opened a new maternity hospital of 32 beds given to the Southport Corporation by Miss Christiana Hartley. The new building is in the grounds of the Southport Infirmary, of which it constitutes an extension, and has cost £25,000. The other extensions of the infirmary, which are now complete, include two additional wards for men and women, and six additional private wards for paying patients. The operating block has been enlarged and modernised, the radiological department has been remodelled, and a nurses' home has been erected. The total cost of the improvements is £67,000.

Hospital Treatment for the Middle Classes.

A meeting was held at King's College Hospital a few days ago to inaugurate a subscription scheme to enable people of the middle classes to obtain hospital treatment without great expenditure. It is a Mutual Benefit Association, on the lines of the Hospital Saving Association, which provides for the poorer classes, and entitles subscribers to 21 days' free treatment in a private ward at the hospital. The rates vary with the number of people concerned, and there is no income limit. The annual subscription for a single person is £1 1*s.*, for a married couple £1 11*s.* 6*d.*, and for a couple with children under 16, £2 2*s.* Subscribers will be required to declare on joining that they are in sound health and that neither they nor their dependents are in need of hospital treatment. The subscriber may make his own arrangement with a member of the consulting staff for the payment of his fees or with the house governor, who is authorised to arrange reduced fees to meet the circumstances

PARLIAMENT

NOTES ON CURRENT TOPICS.

Reassembly of the House of Commons.

THE House of Commons reassembled after the Whitsuntide recess on Monday, May 23rd.

HOUSE OF COMMONS.

MONDAY, MAY 23RD.

Rural Housing.

Mr. THOMAS WILLIAMS asked the Minister of Health what progress had been made with the two million pounds scheme for rural housing initiated by the Ministry in July, 1931.—Mr. E. BROWN (Parliamentary Secretary to the Ministry of Health) replied: 114 Councils have been informed that the committee appointed under the Act of last year are prepared to entertain applications in respect of 1904 houses for the agricultural population, and these councils have for some time been preparing their detailed proposals. Only seven have as yet reached the stage of inviting tenders.

Housing in England and Wales.

Mr. HICKS asked the Minister of Health what was the present estimated shortage of housing accommodation in England and Wales; what was the number of parlour-houses and flats erected in each of the months January, February, and March, 1932; and what action was being taken by the Ministry of Health to urge local authorities to press forward building schemes.—Mr. E. BROWN replied: My right hon. friend regrets that he has no data on which to base such an estimate as is asked for in the first part of the question. Nor is he able to state the total numbers of parlour-houses and flats erected from time to time in England and Wales. The numbers of houses and flats erected with State assistance and completed in the three months mentioned were 6218, 6402, and 5916. As regards the last part of the question I would refer the hon. Member to the answer given to the question put by him on the 12th of this month.

Mr. LUNN asked the Minister of Health how many houses were being built by local authorities in May, 1931, and how many in May, 1932.—Mr. E. BROWN replied: 35,449 dwellings were under construction by local authorities at *April 30th, 1931, and 33,493 at April 30th, 1932.*

TUESDAY, MAY 24TH.

Insanitary Ships in Port of Manchester.

Mr. LOGAN asked the President of the Board of Trade if his attention had been drawn to the fact that more than 30 per cent. of British ships entering the port of Manchester were found to be insanitary; that the death-rate of British seamen was over 70 per cent in excess of the normal mortality-rate; and what action was being taken to improve the quarters of the crew and the sanitation on British ships.—Mr. RUNCIMAN replied: I am aware that the medical officer of health to the port sanitary authority of Manchester has stated in his report for 1930 that of 1324 British vessels entering the port in that year, 395 have been found on inspection to be insanitary. This number covers defective as well as insanitary vessels, and in many cases the ships had small defects, due to voyage damage or wear and tear, which were remedied before the ships sailed again. The action taken to improve the crew accommodation in British ships is indicated in the statement the President of the Board of Trade circulated in the official report of July 7th last. As regards mortality due to disease arising from the character of the occupation, the special investigation, of which this House was informed on Dec. 24th, 1929, has been completed and the report will be published as soon as possible. It will show that the shipping industry does not compare unfavourably with other industries in this respect.

Medical Diary

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

WEDNESDAY, June 1st.—SURGERY. Annual Provincial Meeting at the General Infirmary, Leeds.

FRIDAY.—5.30 P.M., DISEASE IN CHILDREN. (Cases at 4.30 P.M.) Election of Officers and Council.

FRIDAY.—5 P.M., OPHTHALMOLOGY. Election of Officers and Council. LARYNGOLOGY AND OTOLOGY. Summer Meeting at the Eye and Ear Hospital, Portsmouth. Papers: Mr. G. H. Livingstone: The Nasal Airway of the New-born Child. Dr. G. Scott Williamson: The Genesis of Polypi. Mr. Lionel Colledge: Referred Pain. Discussion: Types of Nasal Inflammation which Produce Inflammatory Conditions of the Ear. (Openers: Mr. H. S. Barwell and Mr. Somerville Hastings.)

SATURDAY.—LARYNGOLOGY AND OTOLOGY. Second day at Portsmouth.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.

THURSDAY, June 2nd.—Dr. J. W. McNee: Liver and Spleen—their Clinical and Pathological Associations. (First Croonian lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, May 30th, to SATURDAY, June 4th.—CLINICAL PATHOLOGY, 10, Bedford-square, W.C. Epidiascope and laboratory demonstration by Dr. Knyvett *Gordon* on Wed., at 8.30 P.M., on Splenic Enlargement.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square. Lecture on Epidemic Encephalitis by Prof. Arthur J. Hall, at 8.30 P.M., on Thurs.—ROYAL FREE HOSPITAL, Gray's Inn-road, W.C. *Demonstration of Antenatal Treatment* by Prof. Dame Louise McIlroy on Wed. at 5 P.M.—(The above courses and lectures are open only to Members of the Fellowship of Medicine.)

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

MONDAY, May 30th.—10 A.M. to 1 P.M., Gynæcological Wards, Genito-Urinary [illegible] Skin Department[illegible] Surgical Wards. 2 to [illegible] Wards, Medical, Surgi[illegible] Out-patients. 4.15 P.M. (Special Demonstration, *Mr. Gibb: Eye Cases.*

TUESDAY.—10 A.M. to 1 P.M., Medical Wards, Surgical Demonstration, Thr[illegible] Dental Departments. 2 to 4 P.M., [illegible], and Throat Out-patients.

WEDNESDAY, June 1st.—10 A.M., to 1 P.M., Children's Medical [illegible] Medical *Wards.* 2 *to* 4 P.M., Gynæcol[illegible] al, Surgical, and Eye Out-pati[illegible] Diseases Demonstration.

e with Memorandum 153/M.C.W., of the Ministry Health, the most recent information forthcoming m laboratory research and from the analysis of statistics of birth control clinics. There took ce four sessions. At the first, held on Friday ernoon under the chairmanship of Sir Thomas rder, the President of the Association, a summary s given of researches which may yield the contra- ptive methods of the future. Prof. Lancelot gben and Mr. C. W. Bellerby outlined the relevant rk done up to date on temporary sterilisation by rmonic methods, and Dr. L. W. Cann gave an ount of methods by which a similar result y prove to be obtainable by the injection of rmatoxins. On Saturday morning a session was roted to spermicidal preparations and their effects. . C. P. Blacker began by describing from the chair steps by which the researches conducted in the t four years by the speakers who were to follow n were initiated by the Birth Control Investigation mmittee. These researches were planned with a w to discovering a really efficient spermicidal paration which would enable the woman to dis- ase with the use of rubber occlusive appliances. . J. R. Baker, D.Phil., then described the work has recently done in collaboration with Mr. J. M. lland, D.Sc., which resulted in the discovery of the ry high spermicidal power of quinols and quinones. e biochemical action of these substances and their rivatives is technically discussed in a valuable per by Dr. Gulland in the *Biochemical Journal* 932, xxvi., 32). Six of these have been discovered ich are capable of killing in the course of half an ur guinea-pig spermatozoa in the extraordinarily ute concentration of 1/52,200. Prof. H. W. orey gave an account of his recent work on the hicles or bases in which the chemical spermicide ust be incorporated. It has been proved that ese bases can exert a contraceptive action by echanically impeding the ascent of spermatozoa to the uterus. Lastly, Dr. C. I. Voge described me of the spermicidal preparations with which e market has recently been flooded in Germany, e United States, and this country. Over 100 of ese are now obtainable.

In the course of the afternoon session, under the airmanship of Dr. Killick Millard, a discussion ok place of the methods now in use at clinics. No w data have been collected and analysed since e publication of the fourth report of the Inter- tional Medical Group for the Investigation of ntraception referred to above, which remains the ost complete summary of our existing knowledge at has yet appeared. Mrs. Enid Charles. Ph.D., gave preliminary account of the analysis of three sources statistical material which she has undertaken, the lient outcome of which confirms a finding of the ambridge birth control clinic that the sheath, when roperly used, is the most reliable of all methods.

On Sunday morning a discussion took place on the räfenberg ring, under the chairmanship of Sir umphry Rolleston. Papers were read by Mr. H. M. arleton, Ph.D., who has placed such rings in the uterine orns of over 100 rabbits, and by Dr. Helena Wright. r. Carleton described an interesting and important nding that silver may be chemically attacked in he uterus so as to form silver sulphide, the ring ecoming, in the process, brittle and liable to break. he general consensus of opinion was that the räfenberg silver ring is a dangerous and unreliable ontraceptive, and that if intra-uterine rings are to e used at all for contraceptive purposes, they should e made of gold, which does not form a sulphide, and ot of silver.

The chairman informed the meeting that the ational Birth Control Association was prepared to rrange a similar conference next year, and, if desired, n subsequent years, and a unanimous desire was xpressed that this should be done. Since these onferences will be non-propagandist in aim, and will e limited to the presentation of new information rising from laboratory research and clinical experience, they will certainly prove useful to medical practitioners who are interested in birth control in an administrative or private capacity.

The Seventh International Conference.

The proceedings of the Seventh International Birth Control Conference organised by Mrs. Margaret Sanger and held at Zürich in September, 1930, an account of which appeared in THE LANCET (1930, ii., 650), have been issued in book form.[2] The volume is divided into four parts. The first contains a discussion of various contraceptive methods, including the vaginal and cervical pessaries, the intra-uterine silver ring, and various soluble preparations.

Sections are included dealing with temporary sterilisation by biological methods, and permanent surgical sterilisation. The second part contains a discussion of abortion, and the third consists of reports from birth control clinics in the United States, England, Germany, Russia, Austria, Holland, Denmark, India, China, and Japan. English readers will be interested in an account of the Wives' Clinic at Sholapur, founded by Captain A. P. Pillay in 1929. The latter writes that despite the antagonistic influence of Indian religions, the interference of the mother-in-law even in matters relating to the marital relations of their sons and their wives, the prevalence of polygamy and the fatalism which characterises the Indian outlook on life, " our experience has convinced us that the subject can be popularised in this country as easily as in other countries, provided that funds are available." The fourth and last part of the volume consists of a lucid and impartial summary, compressed into 10 pages, of the first three parts, by Dr. Hannah Stone. The perusal of this book will convince the reader of the progress which the birth control movement has made in this country compared with continental countries. It would indeed appear that one of the objects in Mrs. Sanger's mind in organising the conference was to educate the medical profession in Germany on this subject. The discussions which took place at the different sessions are reported verbatim. An unduly large part in these was taken by German speakers, who were somewhat verbose. The papers on research and the analyses of clinic statistics furnished by the English and American delegates proved to be much more thorough and comprehensive than those forthcoming from any other country. From this book there will not be discovered any new contraceptive method, and little will be gleaned that was not previously known. The conference is likely to attain to historic rather than scientific importance. The translation of the German papers and speeches and the general editing of the proceedings have been very well done.

A Physician's Manual.

For a long time a need has been felt for a book on contraception written not for the layman—many such works exist already—but for the doctor. This need is adequately met by a volume which first appeared in the United States.[3] The author recommends a combination of diaphragmatic vaginal pessary, spermicidal ointment, and douche. The size of pessary most often fitted is of a diameter of 70 mm. In a total of 1014 cases, 790, or 78 per cent., were fitted with such pessaries, and 222, or 22 per cent., with cervical pessaries which were used in cases of retroversion and cystocele. The average length of time during which the appliance was used was between one and two years—a somewhat short period for a satisfactory evaluation. Out of a total of 740 women advised by her, Dr. Konikow kept in touch with, and had reports of, 397, and lost touch with 343. Among the 397 women with whom she

NOTES, COMMENTS, AND ABSTRACTS

BIRTH CONTROL STUDIES.

BIRTH control is a controversial subject on which feelings run high but it is highly desirable that medical men and women should be supplied with accurate information on all its aspects. This is the disarming introduction made by Sir Humphry Rolleston to the Fourth Annual Report of the International Medical Group for the Investigation of Contraception.[1]

Report of the International Medical Group.

The report was published under the auspices of the Birth Control Investigation Committee, which has since become a constituent part of the National Birth Control Association, and aims at being an impartial summary of information bearing on birth control as it becomes available in different countries. According to Dr. Hannah Stone, who supplies a survey of the position in America, a greater change in the temper of the people towards birth control has taken place in the space of the last two years than in the preceding decades. Continued attempts have been made to amend or repeal federal or national and State laws concerning birth control, but many believe that the question will eventually be solved by a nullification of the laws rather than by their change or repeal. An unsuccessful prosecution in 1929 in New York City established the fact in the words of the magistrate, that "If a doctor in good faith believes that the patient is a married woman, and that her health requires prevention of conception, it is no crime to so advise and instruct therein." The prosecution is said to have evoked a vast amount of discussion and helped to crystallise public opinion, not only locally but all over the country. To-day there are over 75 contraceptive services in the States, all under medical supervision. The method still most generally advised at these clinics is a vaginal diaphragm or cervical cap with a contraceptive jelly. For patients with relaxed perineum, cystocele, rectocele, and prolapse, the most inexpensive and simple device is held to be a rubber sponge cut to individual measurements, with the centre scooped out for the cervix. This device has certain disadvantages and improved methods for the application of contraceptive jellies alone are being tried out in these cases. In addition attempts to introduce an effervescent chemical contraceptive in tube form are recorded.

THE GRÄFENBERG RING.

With regard to the Gräfenberg intra-uterine ring no information is available from America, but experiences with it are described by Dr. J. H. Leunbach (Copenhagen), Dr. Helena Wright, and Dr. Norman Haire. Dr. Leunbach's report is not very encouraging. Out of 175 patients to whom silver rings were applied, in 49 cases the ring has had to be removed because of constant bleeding, pain, vaginal discharge, and tenderness; in 35 cases the rings were spontaneously expelled, in most cases several months after the introduction. Only nine of these women themselves noticed that the ring had come out; five women became pregnant because they wrongly believed that the ring was present, while in four additional cases pregnancy occurred although the rings were in the proper place. Less than 50 per cent. of the patients are entirely or even fairly satisfied with the ring after two years' observation, and in some of these menstruation has become somewhat irregular. Dr. Helena Wright reports on a much smaller series of patients, 36 in all (for contraceptive purposes) but her results are equally discouraging. In only nine cases have the rings been successfully retained. In the remainder the ring was ejected at various periods and seven pregnancies resulted. Her conclusion is that the great disadvantage of the method is the uncertainty of the retention of the ring by the fundus, and owing to the extreme irregularity of its behaviour from patient to patient there is no clue as is what is likely to happen in any one case. Dr. Norman Haire reaches much less pessimistic conclusions. With an experience of over 400 cases (the longest period of observation being two years and a quarter) he is convinced of its value in "suitable" cases (undefined), as long as the method is applied only by the gynæcologist. He admits that he has found the ring alone not to be a certain preventive of conception and that in a certain number of cases the ring is expressed by the uterus, but adds that if another ring of different size or different elasticity is chosen one can be found which will stay in. He reports very few cases in which ill-effects were incurred and his general impression of this method is therefore favourable; but as he supports his views with no statistical evidence the results cannot be critically appraised.

SUCCESSES AND FAILURES.

The information about other methods that has become available in Great Britain during the year is very ably summarised by Dr. C. P. Blacker, the editor of the report. He shows that out of a total of 6081 cases advised at eight clinics 5 per cent. resulted in failure—i.e., pregnancy ensued—while 8 per cent. found the method advised unacceptable and abandoned it. It must, however, be noted that these proportions are the *minimum;* they only relate to cases with which the clinics maintained contact without following them up. Mrs. Margaret Lloyd, of the North Kensington Clinic, shows that of 460 "followed-up" cases about 9 per cent. found the method to fail and nearly two-thirds found it unacceptable—i.e., the results are considerably worse amongst the followed-up patients. More or less similar figures are reported from the Cambridge clinic, which instituted a follow-up inquiry, and here a comparison of the figures has led to the conclusion that both as regards proportion of failures and of acceptability the sheath is more satisfactory than the rubber pessary.

Some of the most interesting figures relate to the number of pregnancies that take place after the methods have been abandoned. It is often assumed, consciously or unconsciously, that without prevention 100 per cent. of pregnancies would ensue, and the proportion of successes, for lack of a control group, is really measured on that assumption. If in actual fact a large number of women would not become pregnant without prevention the proportion of successes is obviously overstated. The statistics reported show that actually only half the women who gave up the method advised, subsequently became pregnant, though it must be admitted that no indication is given as to how long they have been "exposed to risk," and information is required on that point.

Blacker includes in this summary an account of J. R. Baker's further studies on chemical spermicides, while Dr. Hertha Riese contributes a study of abortion and suicide in Germany, the thesis being that the practice of abortion is so widespread (an estimate of one million a year is given) that the use of contraceptive methods should be widely extended.

The report is generally a very useful summary of recent information on birth control, although it inevitably leaves the reader with the feeling that both the methods applied and the means of measuring their success or failure remain extremely inexact.

Last Week's Conference.

A conference, organised by the National Birth Control Association, was held in London from May 20th to 22nd at the Caxton Hall. The object of this conference was to place before medical officers of health, representatives of local authorities, and other interested persons who might wish to create facilities for giving advice on birth control in accord-

ADDRESSES AND ORIGINAL ARTICLES

DYSPHAGIA.*

WALTER HOWARTH, M.B. CAMB., F.R.C.S. ENG.,
RGEON TO THE EAR, NOSE, AND THROAT DEPARTMENT, ST. THOMAS'S HOSPITAL; PRESIDENT OF THE LARYNGOLOGICAL SECTION, ROYAL SOCIETY OF MEDICINE.

IFFICULTY in swallowing may occur at any ment after the food (solid or liquid) leaves the uth on its passage past the fauces, through the irynx, down the œsophagus, and into the stomach. ien we consider the normal act of deglutition find that the bolus of food is, by the action of tongue musculature, propelled towards the k of the pharynx. As the contraction of the iohyoglossus and other muscles perform this act, larynx is drawn forcibly upwards by the action these muscles and some of the infrahyoid muscu- ure. This action depends on the integrity of thyrohyoid ligament. This drawing-up of the ynx and the infolding of the arytenoids prevents food entering or even touching the larynx, and enables the bolus of food to reach the deep pharynx. is, which is normally closed, opens to receive it, l the sphincter at the beginning of the œsophagus n relaxes. The food and liquid drops straight wnwards, unless the bolus of food is a fairly big e, in which case it goes down by the peristaltic tion of the gullet wall. The first act is voluntary t may be reflex as in a decerebrate animal allowing is elicited when water or dilute alcohol placed in the mouth: the next two are reflex d are dependent on the peristaltic action of the ophagus; that is to say, on regular waves of ntraction preceded by a wave of relaxation. This ocess continues until the stomach is reached as ere is no true sphincter at the cardiac end of the llet. It will be appreciated that with such a ng passage from the mouth to the stomach, and ith so many structures involved on the way, the portunities for some interference with the normal nditions that may cause difficulty in swallowing e very great.

I do not propose to go into all the causes of sphagia, for that would make rather a tedious talogue and would serve no useful purpose. For is reason I shall say nothing about acute inflam- atory affections of the mouth, fauces, and pharynx, nce everyone is familiar for example with the tense pain and difficulty in swallowing that accom- anies a quinsy and knows what measures are most kely to relieve it. It is the dysphagia of gradual nset that demands our attention, not only on ccount of the discomfort that the patient experiences nd which requires relief, but also as an index of ossible serious disease.

The Mouth and Pharynx.

When a patient complains of discomfort or difficulty n swallowing over any considerable period it is of the reatest importance that a very careful examination f the tongue, pharynx, and larynx be made in the irst instance. In some cases it will be found that ome chronic inflammatory process is the cause of he trouble, thus, for instance, a well-marked *chronic pharyngitis*, particularly the hypertrophic type with swollen lateral bands that is produced by post-nasal discharge, often gives rise to considerable dysphagia. This is not only on account of the inflamed mucosa being sensitive to the stimulus of the food, but also on account of some underlying myositis which may interfere to some extent with proper coördination of the muscular action. Various forms of *ulceration* at the back of the tongue, on the faucial pillars, or in the pharynx may be responsible, and in this connexion I should like to mention *Vincent's angina, syphilis,* and *malignant disease.*

Vincent's angina is much commoner than is usually supposed and causes ulceration of the fauces and back of the tongue which render swallowing difficult, whilst the ulceration due to a breaking down gumma or to a carcinoma often appears far back at the base of the tongue and may escape observation unless a laryngeal mirror is used. Either may, however, involve the pharyngeal wall and impede swallowing very considerably.

There are two other conditions in this region to which I should like to draw attention—namely, *pharyngeal paralysis* and *retropharyngeal abscess.*

PHARYNGEAL PARALYSIS.

Pharyngeal paralysis, especially when slight, is very apt to be overlooked, but it is of great importance that it should be borne in mind, for not only may it account for the dysphagia, but it may also be the first indication of serious disease of the central nervous system. The last four cranial nerves are concerned in the mechanism of speech and swallowing, between which there is a certain interdependence, the act of one inhibiting the act of the other. The nuclei of these nerves are scattered through the medulla, which contains the centre for the deglutition reflex. Degeneration of nuclei within the bulb occurs in the bulbar type of syringomyelia, and dysphagia may be the very earliest symptom of this disease. Other bulbar lesions may also have dysphagia as one of their early symptoms.

The recognition of pharyngeal paralysis is not always easy, but if the posterior wall of the pharynx is carefully inspected and the patient asked to swallow, one side of the pharynx will be seen to move across to the other side, rather like a shutter, the paralysed side being pulled over to the healthy side. When pharyngeal paralysis is observed a laryngoscopic examination may reveal a paralysis of the cord, and the diagnosis of a bulbar lesion be thus confirmed.

In bulbar palsy dysphagia may be an early symptom, not only because of weakness of the pharyngeal muscles during the second stage of swallowing, but also because of loss of power in the tongue so that the food is passed back into the pharynx with difficulty. Myasthenia gravis may give rise to dysphagia and in this case a careful look-out for associated symptoms will probably make the diagnosis certain. It is extraordinary for how long some of these cases go on without getting markedly worse.

I have still under observation a man, after 12 years, whose first symptom was dysphagia associated with hoarseness due to a paralysed vocal cord in whom, after a year or two, an atrophy of half of the tongue supervened. For many years his condition has been stationary and he is still at work, and the bulbar lesion does not appear to have progressed.

The paralysis of the pharyngeal muscles following diphtheria is, of course, well known, and dysphagia following an attack of diphtheria would naturally receive appropriate consideration.

RETROPHARYNGEAL ABSCESS.

Retropharyngeal abscess is usually seen in children as an acute process, but at times it develops in adults kept in touch, there were 18 failures or cases of unwanted pregnancy—12 unaccountable, and six due to an omission of some part of the technique. This figure compares somewhat favourably with the corresponding figure of 5 per cent. of failures for British birth control clinics.

---

* Read at a meeting of the East Sussex Medico-Chirurgical Society on March 10th, 1932.

The book is clearly written and is well illustrated by diagrams and drawings. It is probable, however, that the author under-estimates the value of the sheath as a contraceptive method. She states that her practice shows a high percentage of failures with the use of this method, but she does not specify, in an otherwise full statistical supplement, what this percentage is.

THE DOCTOR AS TEACHER.

AT a meeting of the London Jewish Hospital Medical Society on May 12th, Dr. L. Phillips read a paper in which the doctor was considered as a factor in the movement for public enlightenment. Such activity was almost entirely a modern development. Bacteriology had made manifest the importance of cleanliness in health, a simple measure which could be made effective in every home. Tuberculosis, cancer, and venereal disease were instances of diseases being countered by public campaigns of enlightenment, led and inspired by doctors, as were also the "open-air," "sunlight," and "dress-reform" movements. Maternity and infant welfare centres and school inspection afforded means of direct instruction; and the public lecture, the press, the screen, and the wireless were being more and more extensively utilised. Courses of instruction in health matters were now regularly arranged by many organisations. These activities revealed a change in the mutual relationship of doctor and community. The former was ceasing to regard himself merely as a professional healer of individual ills, plying an exclusive craft; the latter was ceasing to invest the doctor with a priestly halo of mysterious omnipotence. Avowing himself a man of science with frankly confessed limitations, and dispersing the mist of superstition and ignorance which still enveloped popular knowledge of health and disease, the doctor was being less exposed to condemnation and was rising in public esteem. A lessening demand for the inessential was putting efficiency before the bedside manner, and the realisation that the team was the true unit of modern medical practice was contending with the desire for the traditional "personal touch." By satisfying the general desire for enlightenment in health and disease the doctor was exercising a powerful influence in the direction of human progress.

DERMATOLOGY AS AN OUTPOST OF MEDICINE.

IN the fifth Malcolm Morris memorial lecture, delivered last Monday at the Royal Society of Arts, Sir Ernest Graham-Little showed how the position of dermatology in relationship to general medicine had changed out of all recognition within our own generation. He congratulated himself on having been trained in the French school of dermatology at a time when that school was largely overshadowed by its great German rival.

The Austro-German school, founded by Hebra, which reigned through the latter part of last century, attached far more importance to external than to internal causations of skin diseases, but the contemporary French school anticipated modern theories in the importance which it ascribed to general systemic causes. Louis Brocq, in his classical work published in 1907, divided these diseases into two main groups: those which he called "true morbid entities"—i.e., specific diseases of the skin, with an ætiology chiefly external, and a larger group of diseases of the skin which he claimed should be regarded as "cutaneous reactions" to more general causes. This highly philosophic conception became fruitful of new and important modern discoveries, centred round the phenomenon known as "allergy."

The physiological functions of the skin had, Sir Ernest said, become much more understood and had assumed far greater importance within the last few years. It was too often forgotten that the skin was in many senses the largest organ of the body, acting as a protecting medium between the body as a whole and its environment. Physical health was largely a matter of regulating the influences affecting the surface of the body and its movements. It was not therefore surprising that the French conception of skin diseases, as being in the large majority of cases a "cutaneous reaction to general conditions," had in recent years received so great an impetus. The natural corollary of such conceptions was that dermatological eruptions had often become pointers for the recognition of systemic disorders, of which they were indeed only one manifestation. In conclusion Sir Ernest spoke of an endeavour some years ago to persuade the Senate of London University to allow the M.D. examination to be taken in dermatological medicine, thus bringing it into line with other special branches of medicine and surgery in which this is allowed. A member of the Senate then argued that the "cuticle," as he called it, could not compare in importance with the organs of the body in which specialisms were recognised. Yet the skin was, in fact, one of the most important of our means of defence against disease, and its disorders one of the most valuable indications of general illness. The study of dermatology was of essential importance to the medical student, and should be a compulsory item of the curriculum.

JOHN HEAVISIDE.[1]

WHO was John Heaviside? In chronicles of the beginning of the nineteenth century, or thereabouts, his name not seldom occurs, and as he was an interesting person, Dr. G. C. Peachey has done well to compile a little account of his life. A pupil of the famous Percivall Pott, of St. Bartholomew's Hospital, he failed to secure election to the staff of this institution, in spite of his important patronage, for the post which he contested with Abernethy fell to his distinguished rival. None the less, Heaviside attained to a great professional and social position, and it was his fashionable status that led him to be associated with the notorious duel between Colonel Montgomerie and Captain Macnamara, when Montgomerie was shot through the heart, and Macnamara was arrested for murder. Heaviside was the doctor in attendance, and was later taken into custody as an accessory to the crime. Heaviside defended himself successfully, and evidence was given in his favour by the great Nelson among other distinguished persons. Dr. Peachey quotes the following lines from *Nugæ Canoræ*, which indicates the notoriety of the circumstances:—

> This Surgeon so great,
> Was up early and late,
> To tend accidents bloody and cruel;
> Tie artery or vein,
> Or extract from the brain
> A chance bullet, when shot in a duel.

As far as Heaviside was concerned the jury brought in a verdict of "not guilty," their view clearly being that if duelling continued to go on, a doctor had better be in attendance to mitigate the evil. Heaviside made an extraordinary collection of curiosities, and monsters, pathological preparations, casts of faces, and of miscellanea, often rubbish, but including books, manuscripts, paintings, and drawings. He became surgeon-extraordinary to George III., and was elected to the Royal Society on influential medical backing.

---

[1] John Heaviside, Surgeon. London: St. Martin's Press. Pp. 50.

BOVEY TRACEY AND DISTRICT HOSPITAL.—This new hospital, which has cost £3300, all of which has been raised, was opened last week by Mrs. Trelawny. The building comprises four wards, a theatre, and quarters for the matron and staff.

hat spasm may occur at the entrance to the gullet s well as at its lower end, and the train of symptoms hat is met with is usually a very definite one.

Spasm of the Œsophagus.

Spasm at the Upper End.—The patients are almost lways middle-aged women and the outstanding ymptom is difficulty in swallowing which is located t the level of the larynx. The diet is gradually educed until milk, fluids, and eggs are the staple are. Choking fits occur and are dreaded so much that reat care is taken in eating and an hour may be aken in eating an egg and a thin slice of bread and utter. The food taken is insufficient and the patients ecome emaciated. About a third of them are anæmic.

It is found that most of these patients have superficial glossitis and cracking of the corners of the mouth and that these changes may extend to the upper end of the gullet. The association of spasm of the pharyngo-œsophageal sphincter with glossitis, anæmia, and enlargement of the spleen has been recognised for some time in this country and recently a series of cases has been reported in America and the association of symptoms has there been given the name of the Plummer-Vinson syndrome. A cure can usually be effected by the administration of iron and arsenic and the passage of the œsophagoscope to stretch the crico-pharyngeus sphincter.

Spasm at the Lower End.—For many years opinions have differed, often violently, as to whether the spasm and consequent hold-up that occurs at the lower end of the gullet is a true spasm or not. Certainly the structures involved differ very markedly. In pharyngo-œsophageal spasm the muscle involved is striated and strong, whereas at the lower end it is unstriated and yielding, as there is no true sphincter at the cardiac end of the œsophagus. Whether cardiospasm is a correct term or whether we should more properly call it achalasia of the cardia (which means want of relaxation) need not be discussed on this occasion. We are content to recognise the clinical entity. The onset of the disease is invidious and may extend over months or years. The usual complaints are occasional difficulty in swallowing, and, after meals, a sensation of weight in the epigastrium which is relieved by drinking or by regurgitation of the food. The discomfort is often only temporary and is thought to be due to gastric disturbance. At a later stage there is dysphagia and regurgitation of food at every meal, liquids often presenting the most difficulty. Careful inquiry as to the dysphagia will elicit the fact that it is usually referred to the lower end (though occasionally the cricoid may be mentioned), that it is intermittent and varies in degree, normal meals often being taken after one slight hold-up has been overcome, whilst at other times nothing whatever can be swallowed. Regurgitation, the other main symptom, is often wrongly referred to as vomiting. It may occur at every meal or only intermittently. Often regurgitation is immediate and the patient retains no food. Occasionally the regurgitation is excited by the patient himself in order to get rid of the saliva and food that has collected in the gullet; swallowing is then easier. Pain at the cardia and excessive salivation are other symptoms that are complained of.

Examination of the patient at the X ray screen shows a typical picture. The barium meal drops straight to the cardia and is held up there, the dilated œsophagus then fills up and presents a sausage-shaped outline. No fluid may trickle through into the stomach for minutes or hours. Then the cardia relaxes and all the meal goes through quickly.

Œsophagoscopic examination shows an enormously dilated œsophagus, often containing pints of cloudy grey fluid containing soft masses of food. There may be sagging of the dilated gullet so that the gullet seems lengthened and the mucosa is often thrown into folds. The contact of the tube often causes the cardia to shut firmly, but under gentle pressure it usually relaxes and the stomach is entered.

The diagnosis of this affection from malignant disease should not be difficult if attention is paid to the history and careful radiographic and œsophagoscopic examinations are made. Treatment is a matter of great difficulty and the best results are often obtained by forcible stretching of the cardia with mercury filled tubes or dilating bags. The use of belladonna or papaverine is often helpful. Endocrine therapy has improved some patients, but there is a great tendency to relapse and these cases are among the most difficult with which we have to deal.

Organic Causes of Œsophageal Dysphagia.

When we consider organic conditions we have, in the first place, abnormalities of the gullet. I shall mention only one and that is congenital stricture.

CONGENITAL STRICTURE.

This is by no means uncommon, especially that variety in which the lumen is only partially occluded by the web. Sometimes it may go unrecognised for many years.

Some years ago I saw a boy of 4 years of age who had never been able to swallow food properly and who was very emaciated and undersized. On examination of his œsophagus I found a web in the middle third, and the lumen through this was about the size of a large knitting needle. After careful dilatation of the stricture with graduated bougies the lumen was increased in size, so that ordinary food could be swallowed. The boy gained weight rapidly and soon became a normal child. He has been kept under observation for many years, and the œsophagoscope passed occasionally, further dilatation being carried out about every two years.

It is of the greatest importance that the dilatation should be very gradual. If any attempt is made to hurry matters a fatality is certain to occur, as the gullet wall is extraordinarily thin, and overstretching of the stenosis may easily cause a linear tear with subsequent mediastinitis. I have had one case of this nature in which dilatation had been carried out for many years and then, whilst an attempt was being made to enlarge the lumen too rapidly, the gullet wall was split. If the utmost care is used there should be little or no risk of mortality, and the lumen can be enlarged so that any well-masticated food can be swallowed. Congenital stenosis, if not an absolute atresia, yields more readily to œsophagoscopic bouginage than does cicatricial stenosis.

CICATRICIAL STENOSIS.

Cicatricial stenosis or fibrous stricture is met with rarely in this country in comparison with such countries as America or Germany. The reason for this is that in the countries mentioned proprietary washing and cleaning powders containing caustic alkalis are very largely used, and are sold in packets at every grocers without any poison label or even any indication of the contents of the package, so that it is no uncommon thing for utensils which have been used to measure or dissolve the powders to be afterwards used for drinking without rinsing, and thus the residue of the powder remaining is swallowed in strong solution. The accidental swallowing of caustic alkalis is thus a very frequent cause of cicatricial stenosis. In this country household and gives rise to marked difficulty in swallowing. Unless the occurrence in its chronic form is appreciated its presence may well be overlooked. Recently I have had two cases that illustrate this point.

The first was a lady who had marked dysphagia over a period of several months and in whose pharynx I found a soft fluctuating swelling which on examination with the laryngeal mirror was seen to extend as low as the arytenoid. When this was opened and the abscess drained the dysphagia disappeared. The origin of this abscess was obscure but in all probability was due to tuberculous infection of the retropharyngeal gland of Henle.

The other case was a man with a congested beefy-looking pharynx which on closer examination was seen to be fuller on the left side. Examination with the mirror showed a larger swelling on the lateral wall of the pharynx quite low down. Incision produced a quantity of pus and relieved the dysphagia. As the Wassermann reaction was positive it is probable that it was of syphilitic origin.

As these abscesses of retropharyngeal origin tend to track downwards and point in the hypopharynx, they may often be overlooked. If no definite local cause in the region of the pharynx is seen we may have to do with the so-called functional dysphagia. This usually occurs in young females and may be one of the first symptoms of hysteria. It takes two forms —a paralytic and a spasmodic. There is either a difficulty in moving the bolus of food from the mouth into the pharynx (the first stage of deglutition) or else it cannot be passed from the pharynx into the gullet (second stage) and is, as a rule, rejected. Once the food gets into the gullet it passes downwards all right. The complaint of "a lump rising in the throat" or "a ball coming up to meet the food" is a common one.

The diagnosis of functional dysphagia, frequent though is its occurrence, should not be made until all possible organic causes are excluded.

The Larynx.

We now come to the region of the larynx and a consideration of the conditions in this neighbourhood which may give rise to difficulty in swallowing. Apart from the inflammatory affections, it may be said that they are usually of a serious nature. Examination with a laryngoscopic mirror may reveal abnormal conditions in the epilaryngeal region or in the sinus pyriformis. A swollen and infiltrated epiglottis and arytenoids may be due to tuberculous disease, a deep crater-like ulcer due to a breaking-down gumma, or to malignant disease. Dysphagia in such cases may be severe and may often be accompanied by pain which radiates to the ears. The difficulty in swallowing is often an early symptom as any process which causes swelling of the structures at the entrance to the larynx will prevent this from being drawn upwards into the base of the tongue, and the food or fluid will touch the swollen epiglottis or arytenoid, and dysphagia thus occurs owing to undue spasmodic contraction of the pharyngeal musculature. Often fluids present more difficulty than semi-solids or solids.

The Œsophagus.

The gullet begins at the lower border of the cricoid cartilage and is guarded by a sphincter which normally relaxes during the third stage of deglutition. Inspection of this region is beyond the range of mirrors and we have to rely on other methods of examination in order to find out what is the nature of the obstructions that occur. That this examination is important is clear when it is realised that in the œsophagus alone there are to be found at least 30 causes for dysphagia. I need hardly say that I do not propose to deal with all of these, but shall select a few that seem to me to be of importance. When, after exclusion of all possible lesions higher up, it is thought that the cause is an œsophageal one, what are the methods of examination that are at our disposal? They are mainly two: examination by X rays before the fluoroscopic screen and direct œsophagoscopy with suitable tubes. The time has long passed when examination by the blind passage of bougies was justifiable and all examinations of the gullet should be conducted under direct vision.

RADIOSCOPY.

With regard to the X ray examination, it is important that this should be conducted by the surgeon and the passage of the opaque fluid be actually observed. Only by this means can a proper idea be obtained of the behaviour of the various portions of the gullet. Hesitation at the orifice, a slowing at the aortic level, or a complete hold up at the cardia with subsequent filling of the œsophagus above it may all be seen, whilst the passage of the fluid through a stricture, the irregularity or otherwise of the stream, may all throw light on the nature of the obstruction that a single photograph, however skilfully taken, might fail to elucidate. This examination is conducted with the patient upright before the screen and in the lateral position. An examination in the anterior position should, however, never be omitted for by this means one can get an idea of the thoracic organs (heart, lungs, aorta, &c.) and eliminate external pressure on the œsophagus as a cause of stenosis.

ŒSOPHAGOSCOPY.

After the radiographic investigation the patient should be examined with the œsophagoscope. This may be carried out under either local or general anæsthesia. If local anæsthesia is preferred it is well to give the patient an injection of morphine and scopolamine and then to use a 20 per cent. solution of cocaine for the local application. The most effective way of producing the required anæsthesia is to pass the forceps or swab-holder containing the gauze or wool which has been soaked in this solution behind the posterior faucial pillar and then carry it downwards until the pyriform fossa is reached. The superior laryngeal nerve runs across the floor of the sinus, and if the wool is kept in contact with it for a few moments on three occasions at three minute intervals, the surgeon will then be able to pass the œsophagoscope into the gullet without any discomfort to the patient. The patient should be lying down on his back and the head should not be unduly extended. Many people prefer general anæsthesia and it is certainly preferable in many cases, particularly on the first occasion, for a larger tube can often be used and the lower part of the gullet investigated more thoroughly. I have found avertin, administered half an hour before the examination, of very great use, for practically no general anæsthetic is then required.

Are there any contra-indications to œsophagoscopy in the endeavour to locate the source of dysphagia? Naturally the presence of an aortic aneurysm is a definite bar, whilst if it is suspected that the dysphagia may be due to the swallowing of corrosive or caustic fluids, œsophagoscopy should be withheld until sloughing has ceased and the inflammation has subsided. The extremes of age are not a contra-indication.

I should now like to present a few of the œsophageal conditions that may be met with and give rise to dysphagia, but before passing to the various organic conditions which may give rise to dysphagia it will, I think, be advisable to consider spasmodic stenosis of the œsophagus. It is now recognised ue to reflex vagus irritation, whilst hiccup is somemes complained of, particularly when the growth low down. In a large number of cases the degree f dysphagia is not at all severe and often amounts o no more than a vague sense of something being not ust quite right with the swallowing function. If his is associated with occasional choking or coughing, articularly with fluids, and if the subject is elderly, so much time should not be lost in trying palliative measures.

It should be remembered that marked dysphagia, regurgitation, emaciation, and cachexia are terminal ymptoms when the disease has progressed beyond all possibility of cure, and that careful investigation should be made long before such symptoms arise. X ray examination before a fluoroscopic screen may show a hold-up in any of the situations mentioned previously. The hold-up is not absolute but the bismuth will be seen to trickle slowly through the stricture, which often presents an irregular outline. There may, however, be a considerable mass of bismuth held up above the stricture. This may be due to spasm of the gullet wall. If the growth is at the diaphragmatic level, again the growth will probably be seen to be tortuous and a trickle of bismuth to go continuously into the stomach. Sometimes a high stomach growth, that is to say, one involving the abdominal œsophagus just below the diaphragm, may cause a curious appearance, part of the bismuth being held up above the diaphragm and part below.

Œsophagoscopic examination is, of course, essential if an accurate diagnosis is to be made, not only with regard to the nature of the growth but also with regard to its exact situation and extent. It is very unfortunate that in the large majority of cases one does not see the condition in an early enough stage for operative measures to be effective. Occasionally, however, quite early growths are met with. These may be seen on the wall of the gullet with little or no infiltration of it. If such a growth were to appear high up the possibility of excising the growth by incision and exposure in the neck would of course arise. Usually, however, the growth extends a little further down than one expects and, in addition, this part of the œsophagus is not very easy to mobilise. The only place in the thoracic œsophagus where excision is at all possible is about two inches above the diaphragm, and growths seldom appear in this situation.

NON-OPERATIVE TREATMENT.

With regard to other forms of treatment, these consist in the application of radium, removal by diathermy, deep X ray therapy, or the palliative use of intubation tubes.

Not much real success has been achieved by the use of *radium*, though many cases have been treated, and I myself have used it since 1912. The methods of application and the operative technique connected with them have altered and improved considerably, but the results remain frankly disappointing. The radium may be applied as the element in suitable containers, or wrapped round some form of intubation tube so that swallowing may be carried out with the radium in position. Another method is to implant radon seeds into the wall of the œsophagus above the growth and into the growth itself. A third method is to expose the gullet by lateral thoracotomy after having collapsed the lung two days previously. I have done several cases by this method, which not only gives a very good exposure of the lower part of the gullet but also serves to show how hopeless intra-œsophageal attempts at medication may be. When one has exposed the gullet and put one's hand along it, one finds that what seems with the œsophagoscope to be a very small growth is in reality a tumour the size of one's fist stuck on to the aorta and immovably fixed to the root of the lung, so that it is impossible to mobilise it and still less to implant radon seeds completely round it. On several occasions I have obtained considerable temporary relief by merely implanting the radon seeds in the more accessible portions of the growth, as well as using them internally at the same time. It is extraordinary how little discomfort the external thoracotomy gives the patient, and a few days suffice for the lung to expand again.

Deep X ray therapy has not as yet had much of a trial in this country, as there are so few efficient apparatuses in existence here as yet, but it should, I think, give satisfactory temporary results in selected cases.

Intubation.—A large majority of the cases that one sees, particularly those in hospital practice, are so advanced that little remains to be done except to make them comfortable and improve the swallowing for the time being. This is best effected by the use of flexible metal tubes such as Souttar's tube. Any growth that will admit the finest bougie can be dilated sufficiently to take a fairly large tube, and this can remain in position indefinitely. Meanwhile the patient is able to swallow semi-solids and fluids through it with comfort. I have had one patient who wore the tube for 18 months before the growth extended through the mediastinum into the lungs and eventually eroded the aorta. At the post-mortem the metal tube was found still in position in the lumen of the gullet and functioned to the end.

The most distressing feature of carcinoma of the œsophagus, particularly in its terminal stages, is the excessive salivation, and if the stricture is impermeable the constant expectoration every few minutes, both day and night, renders the existence of the patient one of abject misery. A gastrostomy does nothing to relieve this, so that if an intubation tube, however small, can be placed in the middle of the growth and the saliva enabled to trickle through it the comfort of the patient is enormously increased.

Dysphagia due to Pressure on the Œsophagus.

A few words should be said about extra-œsophageal conditions which may press on the gullet and so cause dysphagia. Amongst those that may be mentioned are malignant disease of the thyroid, tuberculous glands, or malignant glands of the neck that may compress the tube in the cervical region. Aneurysm of the arch of the aorta, enlarged bronchial glands, and mediastinal new growths are the most common intrathoracic lesions. In all these cases associated pressure on the recurrent laryngeal nerve may make laryngeal paralysis coexistent and simplify the diagnosis. X ray examination will in most cases be very helpful, whilst in all except aneurysm of the aorta œsophagoscopy is essential.

OUT-PATIENTS' PAYMENTS AT GUY'S HOSPITAL.—Beginning on May 16th out-patients at Guy's Hospital are now being asked to pay a registration fee of 1*s.* on first attendance. Children under 16 will pay 6*d.*, and other charges are fixed as follows: drugs and dressings, 1*s.* per week; massage, 6*d.* per treatment (children 3*d.*); light department, 1*s.* per week; vaccine department, 1*s.*; X ray examination, 2*s.* 6*d.* No charge will, however, be made in hard cases. Last year there were 122,867 out-patients, who made 554,606 attendances. Guy's does not, of course, stand alone in making a small charge to out-patients who can afford to pay it.

ammonia, salts of tartar (potassium carbonate), washing-soda, mercuric chloride, and strong acids when swallowed may give rise to cicatricial œsophageal stenosis. It may also be caused by lesions resulting from syphilis, tuberculosis, typhoid fever, scarlet fever, or diphtheria. When due to the swallowing of corrosive fluids the strictures are often multiple.

It will be remembered that the lumen of the gullet is not uniform throughout its length and that there are three places where the lumen is narrowed: the first is at the entrance which is guarded by the cricopharyngeus, the second where the left bronchus and aortic arch cross it, and the third at the diaphragm. When fluids are swallowed they are apt to touch the gullet wall at these points and consequently stenosis usually occurs at them. The crossing of the left bronchus is the commonest site.

When the stricture has been located dilatation must be attempted. Blind methods of dilatation with the bougie are almost certain to result in death from perforation of the gullet wall, but under œsophagoscopic bouginage the prognosis is favourable as to ultimate cure, the duration of the treatment varying with the number of strictures, the tightness and the extent of the tissue changes in the œsophageal wall. Of recent years attempts have been made to improve the methods of progressive dilatation. One of the newer ways is first of all to perform a gastrostomy and then give the patient a silk thread to swallow. This is eventually brought out through the gastrostomy wound; successive bundles of silk threads are pulled through the gastrostomy opening into the stricture. When the stricture is sufficiently dilated the gastrostomy is allowed to close. Another ingenious method is to have graduated metal olives threaded on the silk in groups of three quite close together in an endless chain which passes through the mouth, down the gullet, through the gastrostomy opening and into the mouth again. The olives, as they pass the stricture, fall into the stomach and are then drawn out through the gastrostomy wound, cleansed, and replaced in the mouth. Treatment may have to go on for months or a year, but the results are most satisfactory.

DIVERTICULA.

The next condition to which I wish to draw your attention is diverticulum of the œsophagus or œsophageal pouch. These occur at the upper end and are really pharyngeal in origin, but the symptoms are mainly œsophageal. The pouch is simply a hernia of the mucosa between the circular and oblique fibres of the inferior constrictor in the region of the lower border of the cricoid. Probably some congenital anatomical factor is responsible for the weakness of the muscle wall in this situation in these cases. Dysphagia is the first symptom and this is followed by regurgitation of the food, or rather that portion that has passed into the pouch. In more advanced cases pressure sensation in the neck and even local swelling when the pouch is filled is felt. This may sometimes be emptied under pressure. Tracheal compression may produce dyspnœa, whilst overflow from the pouch during sleep may give rise to a reflex paroxysmal cough. The X ray appearances when bismuth is swallowed is most characteristic, whilst œsophagoscopic examination will reveal the mouth of the pouch and, lower down, a slit-like entrance into the true œsophagus.

Treatment consists in the exposure of the pouch by incision through the neck and the suturing of its fundus upwards against the pharynx. After adhesions have formed round the neck of the sac and walled off the mediastinum, the pouch may be cut off and the wall invaginated and sutured.

ULCERATION.

Apart from the traumatic form due to the swallowing of foreign bodies or corrosive fluids, ulceration of the gullet is uncommon but may occur in syphilis or tuberculosis. I should like, however, to draw attention to peptic ulcer of the gullet as a cause of dysphagia. These ulcers, which are not as uncommon as is often supposed, occur in the lower part of the œsophagus, and, besides the dysphagia, they may give rise to severe pain in the back with vomiting of blood. Cases have been recorded in which such an ulcer has perforated into the pleural cavity with fatal results. Œsophagoscopy can alone differentiate these ulcers from malignant ones. Treatment consists in the application of silver nitrate to the ulcer and the free use of alkalis. Gramme doses of bismuth subnitrate are said to have a local antiseptic action.

FOREIGN BODIES.

I do not propose to say more than a few words about foreign bodies, though these are not infrequently swallowed, and when they remain lodged in the œsophagus, dysphagia is the most frequent complaint. In the large majority of cases there is a definite history of a foreign body and the diagnosis is not in doubt. The question will always arise as to whether the foreign body is still impacted or whether it has passed on and left some damage to the wall of the pharynx or gullet that may be responsible for the symptoms of dysphagia. In a great many cases X ray examination will be helpful, especially when the metallic bodies are concerned, but a good many objects, particularly fish bones, meat bones, and so forth are non-opaque to X rays. My rule is to wait on events, and if the discomfort persists or increases after two days to advise œsophagoscopy. It is far better to be on the safe side, and that one's examination should be negative, rather than miss some fragment of bone that is impacted in the wall of the gullet and which might give rise later to perforation, with resulting erosion of a vessel or mediastinal abscess. I regard meat or game bones as the most dangerous type of foreign body. It is a mistake to try to force a foreign body into the stomach with a bougie, for on more than one occasion the gullet wall has been ruptured by this method with fatal results. Blind instrumentation, in view of the safety and success of œsophagoscopy, is, I think, always reprehensible.

Malignant Disease of the Œsophagus.

We must now turn our attention to malignant disease, as this unfortunately provides the majority of cases of dysphagia that are met with. Carcinoma of the gullet is commonest at the lower end and rarest at the upper end, but it is, I think, that which occurs at the aortic level which is often most prominently before us, as the signs and associated symptoms often bring about its recognition at an earlier date, whilst carcinoma at the lower end may present almost no symptoms until it is almost in its terminal stages.

Dysphagia is the commonest symptom and very often the onset is sudden. Sometimes it may come on as a choking fit at meal-time, and often, when the growth is low down, the feeling of obstruction may be referred to the cricoid region, so that the patient's sensation with regard to the site of obstruction is by no means trustworthy. It is a common thing for pain to be referred to the lower end of the sternum. Sometimes an early symptom is paroxysmal cough

ROF. KETTLE AND DR. HILTON: THE TECHNIQUE OF EXPERIMENTAL PNEUMOCONIOSIS.

THE TECHNIQUE OF EXPERIMENTAL PNEUMOCONIOSIS.*

BY E. H. KETTLE, M.D., F.R.C.P. LOND.,
PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF LONDON: PATHOLOGIST TO ST. BARTHOLOMEW'S HOSPITAL;
AND
R. HILTON, M.D. CAMB., F.R.C.P. LOND.,
ASSISTANT PHYSICIAN AND ASSISTANT DIRECTOR OF THE MEDICAL UNIT, ST. BARTHOLOMEW'S HOSPITAL.

(WITH ILLUSTRATIVE PLATE.)

A GREAT deal has been learnt about the pathology of silicosis from the study of human material, but there are still wide gaps in our knowledge. For example, even in simple uncomplicated silicosis it is not yet absolutely clear how the characteristic lesion is produced, nor can we claim exact knowledge of the way in which the tubercle bacillus reacts to the presence of silica in the lung. It is possible that these and other questions could be solved by observation alone, but many of the industrial pulmonary diseases present problems of such complexity that only by experiment are we likely to make progress in their comprehension and control. This has been recognised by all who have worked in this field, and experimental studies have been pursued in this country and abroad for many years.

Exposure to Dusty Atmospheres.

For the direct study of pulmonary lesions the method adopted by practically all experimenters is to expose animals for varying periods of time to dusty atmospheres produced either in boxes or in actual rooms, and this would seem the most obvious technique to employ, for it imitates the natural conditions to which industrial workers are subjected. Nevertheless it has several disadvantages, some so serious as to limit its practical value very considerably. It may be that the method is irreplaceable for the investigation of the earliest pulmonary reactions to particulate matter, the behaviour of phagocytes to different dusts, and so forth. But we are to-day vitally concerned with the production of actual dust lesions in the lungs of experimental animals, because before we can study how the action of silica in the lung may be modified by the presence of other dusts or by infection, we must be able to reproduce the pure silicotic lesion in our experimental animals, and the production of experimental silicosis is the necessary preliminary to the investigation of the toxicity of the other dusts which occur in industries. L. U. Gardner and his colleagues have produced recognisable silicotic lesions in the guinea-pig and the rabbit by the inhalation method, but they make it quite clear that results cannot be obtained unless the animals are dusted continuously for periods measurable in years rather than months, and herein lies the main difficulty of the method. By various mechanical devices it is possible to produce in a confined space an atmosphere containing the appropriate concentration of suspended particulate matter, and the maintenance of such an atmosphere for a period of years is merely a matter of organisation, though it must depend for its success on the coöperation of laboratory assistants who are more than usually reliable. The number of animals used in each experiment must be large to compensate for the wastage which is sure to occur. H. S. Willis[1] has noted the high mortality of dusted animals as compared with controls kept under ordinary laborato conditions. Of a batch of 75 guinea-pigs which were dusted for between two and three years, only 18 were alive at the end of this time. Here, again, the ca[illegible] and identification of a hundred or more animals for a period of years is merely a matter of organisation, and no doubt one experiment of this kind could be carried out without any great difficulty. But it would be impossible to conduct simultaneously a series of such experiments in any ordinary laboratory, and unless the further experimental investigation of these diseases is to be restricted to a few institutions unusually fortunate in regard to space, equipment, income, and personnel, some other technique must be adopted.

LEGENDS TO ILLUSTRATIONS ON PLATE.

PROF. KETTLE AND DR. HILTON.

FIG. I.—Lung of a guinea-pig killed 14 days after intratracheal injection of kaolin; macrophages and syncytial cells lying free in alveoli.

FIG. II.—Lung of a guinea-pig killed on the 330th day after intratracheal injection of a large dose of kaolin. The lung is practically solid with phagocytes containing kaolin crystals, but no reaction of the pulmonary tissues has yet occurred.

FIG. III.—Three nodular collections of phagocytes containing quartz crystals in the lung of a rabbit killed on the 385th day after intratracheal injection of quartz.

FIG. IV.—One of the nodules in Fig. III. under high magnification, showing early increase in collagen.

FIG. V.—Characteristic early silicotic nodules in tracheobronchial lymph gland of a rabbit killed on the 557th day of the experiment, having had three intratracheal injections of quartz.

FIG. VI.—A high magnification of part of Fig. V., showing the development of the laminated silicotic nodule in an early stage.

Direct Intratracheal Injection.

Some years ago one of us becoming dissatisfied with the dusting technique began to experiment with direct intratracheal injections. Unfortunately this work was interrupted but not before indications were obtained that the method had possibilities. It was found that rabbits and guinea-pigs tolerate the introduction of suspensions of particulate matter into the lung by way of the trachea surprisingly well. And the lungs of such animals killed at varying times after the inoculations showed microscopic pictures comparable with those found in animals to which similar dusts had been administered by inhalation. These experiments were cut short, and the animals were killed before pulmonary lesions had time to develop, but during the last three years we have gone further into the matter and have obtained results which are distinctly promising.

TECHNIQUE.

This communication is concerned with the technique we have elaborated. As our suspending fluid we use sterile normal saline solution and to this is added the appropriate quantity of the dust it is desired to introduce, the suspension being freshly prepared and autoclaved before use.

The animals are anæsthetised by urethane, the trachea is identified by palpation, and a nick is made in the skin over it. The trachea is then exposed by blunt dissection aided, if necessary, with a few snips with a pair of scissors, and the needle is thrust into it in a downward sloping direction. The animal is raised to a vertical position and the suspension is injected under gentle pressure. The introduction of the fluid, and even the mobilisation of the trachea, is often followed by one or two coughs, and there may be some regurgitation through the nose, but the greater part of the inoculum passes directly into the lungs. The needle is then withdrawn and the skin incision closed with a catgut suture. Beyond damping the skin with methylated spirit, more for the purpose of controlling the fur than for any other reason, no special precautions are taken against sepsis. We have not found it necessary to apply anything in the shape of a dressing, and we have never observed any local infection. It is possible, of course, to insert the inoculating needle directly into the rabbit's trachea through the uncut skin, and the same can be done, though with much less certainty, in the guinea-pig. But it is also easy to miss the trachea unless it is fully exposed, and since one of our main objects was to use as few animals as possible, we preferred to be quite certain that all our injections actually reached the lungs. We have found, however, that excessive manipulation of the tissues of the neck especially in guinea-pigs is likely to be followed by a heavy mortality in the early days of the experiment. The more rapidly and cleanly the inoculations are performed, the fewer are the immediate casualties, and in our later experiments we have lost relatively few animals—about 10 per cent.

FIG. II.—Calcification of popliteal artery in a case of intermittent claudication. The tibial artery and the dorsalis pedis and its branches also showed extensive calcification.

FIG. III.—The left coronary artery and its branches injected with lipiodol.

FIG. IV.—Post-mortem radiogram of heart showing calcareous atheromatous degeneration of coronary (white patches).

In our early experiments we used dilute suspensions and injected relatively large doses, but recently we have used thicker suspensions, 3 or 4 per cent., and have injected only 1 to 2 c.cm., with apparently much better results. When using such thick suspensions there is always the danger of clogging the larger air passages, but this can be avoided by injecting a little air after the inoculum, thus blowing the fluid into the alveoli. With many dusts it is convenient to inject with an ordinary record syringe and needle, but some of the crystalline preparations tend to stick between the barrel of the syringe and the plunger, and with these it is more convenient to use a glass tube and a large rubber teat, connecting the tube to the needle by thin rubber tubing.

With this method it is easy to inoculate 20 to 30 animals in an hour with amounts of dust which compare very well with the quantities inhaled after many hours in the dusting chamber. If desired the inoculations can be repeated at, say, monthly intervals, and some of our animals have received three or four separate doses.

ADVANTAGES OF THE METHOD.

Once the animal has survived the inoculation it is subjected to no more risk than any member of the laboratory stock; its expectation of life is equally good, and, in fact, we have very few casualties among our animals after the first month of the experiment. The advantages of this method are self-evident; the necessity for the cumbersome dusting plant is avoided, and the laboratory staff is relieved from the supervision of the daily dusting of large numbers of animals over a period of years. The actual number of animals used can be reduced to a minimum. In an experiment involving 30 guinea-pigs, for example, one would expect to have at least 20 to 25 animals alive at the end of three months, and apart from accidents and laboratory epidemics there is no reason why any of these survivors should die except of old age. Again, there is no necessity for the large amounts of dust which the dusting chamber demands; quite small quantities are sufficient, in itself a matter of some importance, and the economy of the method makes it possible to carry out several different experiments simultaneously. We have at present a series of nine experiments in progress, each involving the use of separate dusts or combinations of dusts, and this would have been quite impossible if for each experiment a separate dusting chamber had been required. These advantages, however, fade into insignificance unless it can be shown that the method gives results which can stand comparison with those of the older technique. Our work has not been in progress sufficiently long for us to have produced anything like end-results. Silicosis is a chronic condition taking years to develop, and there is no known method by which the characteristic fibrosis can be accelerated. But so far as they go our results show that the method fulfils certain fundamental requirements.

1. The introduction of the dust suspension into the lungs in the quantities described causes no recognisable trauma of the pulmonary tissue, and there is no apparent difference between the reaction of the lung to dust introduced in this way and dust which is inhaled. Fig. I. is taken from a section of the lung of a guinea-pig killed 14 days after intratracheal injection of 3 c.cm. of a suspension of kaolin. (After removal from the body the lungs in this and the other experiments were distended and fixed with formal saline solution injected through the trachea.) The lung is in no way disorganised. Numerous macrophages and syncytial cells containing kaolin crystals are seen lying free and evenly distributed in the alveoli. The appearance corresponds with that seen in dusted lungs.

2. A very high dust saturation of the lung can be brought about though its distribution may be patchy. Fig. II. is taken from the lung of a guinea-pig killed on the 336th day after the intratracheal injection of a large dose of a concentrated suspension of kaolin. In the part illustrated the lung is practically solid, the alveoli being filled with phagocytes containing the large kaolin crystals. There is as yet no reaction of the actual pulmonary tissues.

3. Dust introduced into the lungs by this method produces lesions which appear to be quite characteristic.

Our earlier results were rather disappointing, since we failed to produce lesions in what we hoped would have proved sufficient time for dusts to have caused fibrosis.[3] But it appears that however the silica reaches the lung, whether as a single massive dose or in repeated inhalations, time is an essential factor in the reaction. Our later results are much more promising, for example:—

Fig. III. is from the lung of a rabbit killed 385 days after intratracheal injection of 5 c.cm. of a suspension of powdered quartz. The section shows three nodular collections of phagocytes, many of which contain quartz crystals.

3. Dust introduced into the lungs by this method produces lesions which appear to be quite characteristic.

Our earlier results were rather disappointing, since we failed to produce lesions in what we hoped would have proved sufficient time for dusts to have caused fibrosis.[3] But it appears that however the silica reaches the lung, whether as a single massive dose or in repeated inhalations, time is an essential factor in the reaction. Our later results are much more promising, for example:—

Fig. III. is from the lung of a rabbit killed 385 days after intratracheal injection of 5 c.cm. of a suspension of powdered quartz. The section shows three nodular collections of phagocytes, many of which contain quartz crystals.

Fig. IV. is a drawing of one of the nodules under a higher magnification; it shows the early increase of collagen, the first stage in the formation of the typical fibrous nodule.

Fig. V. is from the tracheo-bronchial lymph gland of a rabbit killed on the 557th day of the experiment; it had received intratracheal injections of quartz suspensions on the 1st, 158th, and 217th days. The gland shows characteristic early silicotic nodules.

Fig. VI. is a drawing of a higher magnification of a part of the lesion illustrated in Fig. V.; it shows the development of the *laminated silicotic nodule in an early stage*.

Conclusions.

1. A technique is described for the introduction of dust into the lungs of experimental animals by intratracheal injection.
2. The reaction of the lung to dust introduced by this method is essentially the same as to dust introduced by inhalation.
3. The results obtained indicate that the direct intratracheal injection of dust into the lungs may advantageously replace the dusting chamber for many purposes for which it has hitherto been considered necessary.

LYMPHATIC LEUKÆMIA,

WITH INFILTRATION OF PERIOSTEUM SIMULATING ACUTE RHEUMATISM.

By F. J. Poynton, M.D., F.R.C.P. Lond.,
PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL AND SENIOR PHYSICIAN TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET;
AND
Reginald Lightwood, M.D., M.R.C.P. Lond., D.P.H.,
MEDICAL REGISTRAR AND PATHOLOGIST TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET.

(WITH ILLUSTRATIONS ON PLATE.)

We are publishing this case in continuation of the study of unusual features that may be met with in children suffering from conditions such as leukæmia, grave anæmias, and lymphadenoma. A paper previously published in this journal has dealt with osseous and arthritic manifestations in two cases [1]; another dealt with the occurrence of infective granulomata with streptococcal infection.[2] Though such cases are quite unusual, they serve a useful purpose for those who are particularly interested in the diseases in question. Furthermore, the case we are about to describe is one of no little clinical interest on account of its differential diagnosis.

CASE HISTORY.

A girl, aged 3 years and 7 months at the time of her death, was the fourth child of healthy parents, and there was nothing significant in the family history. Measles and pertussis occurred at about the age of 12 months. She contracted chicken-pox three months before admission to hospital, and after this her appetite became poor.

History of illness.—The first symptoms of leukæmia began seven weeks before her death. There was a complaint of pains which flitted from joint to joint, beginning in the knees and going to the ankles, wrists, and finger-joints in turn; only one or two joints were involved at a time. Her temperature was found to be 101° F., and she sweated when asleep. Two weeks after the onset she developed a slight cough. Ten days before admission one ankle became swollen and tender and the doctor in attendance made a diagnosis of acute rheumatism. The swelling of the ankle subsided, but later it was noted that she did not move her left arm freely, though she could use the hand. In the days immediately before admission there was some vomiting and epistaxis.

On *admission* she was found to be very ill, and in fact she only lived six days. There were large purpuric spots on the trunk and limbs and she was deathly pale. Her left arm was held to her side, and she resented being handled. There was œdema of the ankles and of the feet. The pulse was rapid (132–156); there was a short, sharp first sound followed by a systolic bruit at the apex, and a systolic bruit at the base. Her temperature ranged between 99° and 102° F., but fell to normal on the third day in hospital. Her systolic blood pressure was 100 mm. Hg, and her diastolic 55 mm. The edge of the liver was to be felt one finger's breadth below the right costal margin, and the tip of the spleen was palpable. There were no changes in the central nervous system and the fundi were normal.

The *blood picture* was that of an aleukæmic phase in acute lymphatic leukæmia: Red blood-cells, 1,125,000 per c.mm.; hæmoglobin, 15 per cent.; colour-index, 0·43; white blood-cells, 4700 per c.mm.; differential count: 846 polymorphs per c.mm. (18 per cent.) and 3854 lymphocytes per c.mm. (82 per cent.). The lymphocytes varied much in size and shape; there were no other abnormal cells. The red cells showed poikilocytosis, anisocytosis, and polychromasia. There were 10,320 platelets per c.mm. The coagulation time was 2 minutes 40 seconds, and the bleeding time over 10 minutes.

For some years we have been interested in the bone changes occurring in the blood diseases and a radiological examination of the long bones was made as a routine, but in this particular case the pseudoparesis of the left arm, the tenderness of the limbs, and the history of joint swellings would in any case have called for special investigation. Skiagrams of the long bones, taken by Dr. B. Shires, showed uniform periosteal changes in the femora and humeri (Figs. I. and II.). These changes resembled the appearances seen in chronic periostitis. They could not in this patient have been mistaken for syphilitic osteoperiostitis, scorbutic subperiosteal hæmorrhages, or any ordinary chronic infective condition, and it was thought most probable that they had been produced by subperiosteal leukæmic infiltration.

AUTOPSY.

The body was that of a pale child with purpuric spots on the trunk. Enlarged lymphatic glands were to be felt in the axillæ, neck, and groins. The bones felt normal to the examining finger.

Except for pallor of the brain, the cranium and intracranial structures were normal. The cervical glands were enlarged, pale, and discrete. On opening the thorax the lungs were found to be pale and œdematous, petechial hæmorrhages were seen in the pleura. The lymphatic glands at the root of the lungs were enlarged, and on close examination minute white dots were seen under their capsules. A microscopical section of one of these glands showed that its structure was intact, but under the capsule were to be seen numerous hypertrophied cortical lymphatic nodes. It was these bodies which could be seen macroscopically as white dots through the capsule. These dots were also recognisable on some of the enlarged paratracheal glands. The *heart muscle* was found to be soft and flabby, the right ventricle dilated, the valves normal, and the blood clot very pale. Petechial hæmorrhages were to be seen in the pericardium.

On opening the abdomen it was found that the peritoneum and intestinal tract were normal. The mesenteric glands were slightly enlarged, and one of them was caseous (tuberculous). The preaortic glands were enlarged, being two or three times their normal size. The liver was pale and showed slight venous congestion. Microscopically there was extreme fatty degeneration, mainly of the peripheries of the hepatic lobules, and a few aggregations of 20–30 lymphocytes were to be seen. The spleen, firm and slightly pale, was not enlarged. Microscopically there was a slight ease of its trabecular tissue; the lymphocytes were eased and the erythrocytes reduced. The kidneys were e and showed cloudy swelling of the tubules. In one ce numerous dilated vessels were seen in close proximity an aggregation of lymphocytes, but elsewhere the kidney s bloodless. The suprarenals were found to be normal.

Striking pathological changes were seen when the nora and humeri were split open longitudinally. ch of these bones presented the following general anges:—

1) Along the greater length of the bone a layer of the tex was split from the shaft, parallel to the periosteum. e separated bony layer, which was firmly attached to the riosteum, was rather more than 1 mm. thick. Micropical examination of a decalcified section, stained with in and hæmotoxylin, showed that in places the periosteum s infiltrated with lymphocytes and separated from the rtex by new cancellous bone and osteoid tissue.

(2) At the ends of the diaphysis the marrow was pale and cessively trabeculated.

(3) In the marrow cavity were to be seen elongated kæmic deposits, whitish in colour, and firm to the finger. me of these were softened, and bordering the softened eas there was a zone of gelatinous marrow and evidence ggesting increased erythropoietic activity. The softening s most obvious at the lower end of the left humerus. In is situation the epiphyseal line was hardly recognisable, d there had been *absorption of the bony cortex* (Fig. I.). microscopical section of one of these leukæmic deposits the marrow cavity was examined and found to consist deeply staining lymphocytes, many of which were there were small areas of hæmorrhage. ed and this showed, on a smaller scale, g of the periosteum and laying down bone outside the cortex. The other changes remarked pon in the humeri and femora were not seen. The mporal, parietal, frontal, and occipital bones showed no bnormalities.

No organisms were seen in sections of a leukæmic eposit from the bone-marrow (stained by Gram-Veigert's method and by methylene-blue). Cultures aken from the lymphatic glands and the bone-marrow eposits were bacteriologically sterile, the material eing incubated aerobically and anaerobically on eart digest broth and on glucose broth, and also eing inoculated intravenously into a rabbit, without esult.

THE BONES IN SEVERE ANÆMIAS.

That the bones will be affected in certain cases of leukæmia and severe anæmia is to be expected if we consider the anatomy and physiology of the bone-marrow. In the adult human subject the marrow of the long bones is predominantly yellow, and there is a large reserve available for blood formation which is not used under normal circumstances. The large area occupied by resting marrow is remarkable and it indicates how wide a margin has been provided by nature against possible needs. The bulk of the marrow in the adult is estimated to be about 1420 c.cm., which is 13 times the volume of the spleen and almost equal to that of the liver.[3] In the child the marrow of the long bones is much more active than in the adult, and the fact that the marrow of the femur remains red until the age of 12–14 years illustrates this point.[4] It follows that the marrow reserve in the child is relatively small. In both adult and child any extension of hæmopoietic activity can only take place physiologically at the expense of the marrow fat, because the cavity of the bones is entirely filled with tissue. When the demand made on the marrow is very great, and its response has reached a physiological maximum, any further blood requirements can only be met pathologically and in one of two ways: First, by the formation of extramedullary marrow in unusual situations. This is observed in pernicious anæmia, &c., and has been recorded also in fatal cases of the hæmolytic anæmia of acholuric jaundice.[5] Secondly, by the absorption of bony cortex and expansion of the marrow cavity. This has been seen in dogs after repeated hæmorrhage[6] and after splenectomy,[7] and has occasionally been demonstrated radiologically in blood diseases in children.

Absorption of the cortex of the bones has been reported in leukæmias,[8] [9] when it may be the result either of an excessive demand for new blood formation or due to an invasion of the bone by leukæmic tissue. Greig [10] holds that in such cases of leukæmia, osteoporosis and absorption of the cortex may be followed eventually by osteo-sclerosis. Such osteosclerotic changes occurred in a case of leukæmia described by Schwarz.[11] In Albers-Schönberg's disease (osteosclerotic anæmia) the peculiar "marbling" of the bones is of great interest to the surgeon and to the radiologist, but the interest of the hæmatologist is focused on the severe aplastic anæmia sometimes resulting in these cases from thickening of the cortex and encroachment on the marrow spaces. This osteosclerosis is the underlying pathological process and the anæmia is secondary to it. On the other hand, in these leukæmias, which are accompanied by involvement of the bones, the osteosclerosis is the final stage of that involvement, and must be regarded as secondary to the leukæmic process. This is a distinction which, according to Greig, should be drawn between these two varieties of osteosclerosis associated with anæmia.

Vogt and Diamond [12] have made a radiological study of bone changes in certain children with pathologically hyperplastic bone-marrow. They point out that the changes will be less marked in the leukæmias and more marked in the congenital anæmias such, for example, as congenital hæmolytic anæmia (family acholuric jaundice), sickle cell anæmia, and Cooley's erythroblastic anæmia. These changes consist essentially of a thinning of the cortex with expansion of the shaft but localised erosion of the cancellous bone by marrow tissue also occurs. Wollstein and Kreidel [13] have dealt with the bone changes met with in the hæmolytic anæmias of childhood, and one of us (F. J. P.) has (with A. Moncrieff) recorded such changes in lymphatic leukæmia and in lymphadenoma.[1]

We have been able to find only one radiological account of periosteal changes in leukæmia (Taylor[14]). This case was reported from the Roentgenological Department, Beth Israel Hospital, New York City, and presented features very similar to those of our own patient.

Age 2 years and 10 months. Seven months previously the child went off its legs and the mother noticed that both feet and both forearms were hot, swollen, and tender. Two months later pallor was noted. When admitted the child was found to be a case of lymphatic leukæmia. The extremities could be moved but they were tender. The roentgenograms of all the long bones, including the metacarpals and metatarsals, showed a slight elevation of the periosteum with some productive changes. The autopsy confirmed the diagnosis of lymphatic leukæmia and the microscope revealed lymphatic infiltration underneath the periosteum of the tibia and replacement of bone-marrow.

DIFFERENTIAL DIAGNOSIS OF ACUTE LEUKÆMIA WITH CHANGES IN THE BONES.

There is much practical interest in recalling some of the maladies in which pains in the limbs are a feature in children's illnesses, conditions such as scurvy, syphilitic osteoperiostitis, acute leukæmia, rheumatism, and osteomyelitis, to which also may be added those cases of infantile paralysis in which neuritic pains are predominant. We have reproduced here, in illustration of these pathological states, skiagrams which show the periosteal changes that occurred (1) in our case of acute leukæmia (Figs. I.

and II.), (2) in a case of congenital syphilis (Fig. III.), and (3) in a case of scurvy (Fig. IV.). In passing, we would note that scurvy has apparently become more frequent in its occurrence of recent years.

Each of the diseases which we have mentioned above may be confused with one another in diagnosis —thus scurvy may be called rheumatism, acute leukæmia thought to be rheumatism or even scurvy, and the same may occur occasionally with infantile paralysis. Osteomyelitis, as we all know *too* well, may be most difficult to distinguish from rheumatism, particularly when it is multiple and subacute.

No one doubts that the fully developed diseases are widely different and all recognise the dietetic errors and hæmorrhages in scurvy, the early age and stigmata of congenital syphilis, the multiple symptoms and arthritis of acute rheumatism, the extreme anæmia and altered condition of the blood in acute leukæmia, the localised tenderness, severe illness, and high fever of osteomyelitis, and the paralysis which develops later in anterior poliomyelitis.

It must be admitted, however, that at the bedside there are, in some unusual cases, remarkable resemblances between acute leukæmia, virulent rheumatism, and malignant endocarditis. In all there may be a great pallor and in all purpura. The first sound of the heart in acute leukæmia may be so short and sharp as to suggest a mitral stenosis and be followed by a systolic murmur that can be traced to the axilla. At the base there may be a systolic and even diastolic murmur audible. All show fever, all may have pains in the limbs, and all enlarged spleens. The blood picture is, it is true, very different, but in those cases of leukæmia in which there is a leucopenia skilled examination, which is not always at hand, is needed to show the breakdown in the differential count. The undoubted fact remains that, once started on the wrong track, there may be much difficulty in escaping from the diagnosis of virulent rheumatism to that of acute leukæmia, particularly should the tissue around the joints be swollen and tender as in the case we have described.

We are greatly indebted to Dr. B. Shires for taking the skiagrams which illustrate this paper.

PRIVATE WARDS AT MAIDENHEAD.—Arrangements for private wards have now been made at Maidenhead Hospital. In return for an annual subscription varying from £1 1s. to £2 2s., according to family, the subscriber will be entitled to the use of a private ward with free maintenance and nursing; doctors' fees will be a matter of arrangement. There is no income limit and no limit of stay, but a patient must have a certificate from a member of the honorary medical staff that the case is suitable for hospital treatment. Should a private ward not be available 15s. a day up to 21 days will be paid to any other hospital or nursing home to which the patient may go.

CALCIFICATION OF THE ABDOMINAL AORTA,

WITH A REFERENCE TO ATHEROMA AND THE RADIOLOGICAL INVESTIGATION OF ARTERIES.

BY G. E. VILVANDRÉ, M.R.C.S. ENG.,
RADIOLOGIST TO THE LONDON HOSPITAL.

(WITH ILLUSTRATIONS ON PLATE.)

DEPOSITS of calcium salts in arteries may render them visible to the radiologist. Peripheral vessels, especially of the leg, are often demonstrated in Paget's disease (osteitis deformans). In other subjects, too, the arteries in the limbs or the tortuous extracranial ones can also be seen when calcified. Flakes of calcium may sometimes be observed in the arch of the aorta, especially in the transverse portion where the so-called "knuckle," sharply demarcated against the translucent lung, favours their detection. Sharp negatives show narrow crescentic shadows in the outline of the aorta.

The case reported exhibits an unusual degree and extent of calcification of the abdominal aorta, and justifies some remarks upon its detection. It also led me to investigate the natural* though pathological visibility of vessels. Kohler mentions that deposits of lime may be seen in the descending thoracic aorta, and he says that calcified coronary arteries have never yet been demonstrated. I found no mention of a calcified abdominal aorta in his book, but Gibson refers to a case under his care where, under X rays, calcification of *that* vessel was seen to be present in a woman of 68 who complained of abdominal pains which occasionally spread down the inner side of the thighs. He suggests that this may be due to calcification of the aorta.

Calcareous deposits are not evident in radiograms of simple syphilitic aortitis, though they may occ when atheroma supervenes. Small flakes of lime may sometimes be seen in the innominate artery, but they should not be mistaken for minute tubercular deposits (Kohler). In his book Assman shows a patch of calcification (*Kalkplatė*) at the ao- knuckle in a case of arterio-sclerosis. These plaques are due to a localised or patchy thickening of the intima.

Atheroma in the aorta and its bigger branches appears as nodes of different sizes; at first there are translucent or gelatinous plaques, which later become firm or calcareous, and in that state may become demonstrable radiologically. Atheroma of the aorta may be present with healthy coronary arteries. Calcification in the ascending aorta occasionally leads to narrowing or complete occlusion of the orifice of one or both coronary arteries. In the post-mortem room aortic atheroma with calcificati is often seen, while calcification of the cardiac a is less common. The former is a common finding in subjects past middle life.

Among remarkable cases of coronary disease, Jamieson and Hauser reported the case of a boy of 18 who had agonising pain in the chest and died suddenly. At the necropsy coronary throm and calcareous changes, and microscopically a proliferative endarteritis, were found. In Buerger's case the patient was a man of 21 years of age with thrombo-angiitis obliterans, who died following an operation mesenteric thrombosis. Post mortem, marked eroma of the coronary arteries was present. other patient, aged 24 years, is also reported by erger. This patient died suddenly after an amputaion of the right thigh, and post-mortem atheroerosis of the coronary arteries was found. At the int of origin of the right coronary artery (on the ht posterior sinus of Valsalva) was an atheroatous plaque, which narrowed the orifice of the tery even to obstruction. Hughes and Berry ported that a female child of 7 weeks had a sudden tack of cyanosis, and rapid death ensued. Marked ickening and tortuosity of the coronary arteries, hich stood out from the heart like cords, was found, id some patches of calcification were present in the lmonary artery.

---

* Natural as distinct from the injection of opaque substances in vessels.

THE CLINICAL PICTURE.

In many instances where aortic atheroma is present o clinical symptoms are complained of during life. he blood pressure may be raised only slightly or ot at all. Gibson quotes Huchard and Pal, who escribed a syndrome "angina abdominis" which hey ascribed to a non-syphilitic lesion of the abdominal aorta. Gibson further mentions a case described y Louis Ramond, where very painful cramps lasting rom half to two hours were present. No sign of isease of the alimentary tract was evident, neither tone in the kidney nor in the gall-bladder, but adiologically dilatation of the abdominal aorta above ts bifurcation was present, and a dark band indicaive of the thoracic aorta above the diaphragm. The blood pressure was not raised (150 max., 100 min.).

Coronary atheroma, on the other hand, more often causes symptoms, but so far has not been demonstrated radiologically except by Lenk, and one object of this communication is to stimulate some interest in the investigation of the coronaries, from a radiological point of view.

It is now acknowledged that most cases of angina pectoris have as their basis atheroma of the coronary vessels. "It must be remembered," says Mackenzie, "that changes similar to those that have affected the aorta may have affected the coronary arteries." When this condition is present, narrowing or even occlusion in the course of the coronaries may occur, or the narrowing may eventually determine a thrombus with resulting occlusion and cardiac infarction.

Vaquez and Bordet refer, under the diagnosis of arteritis and of atheroma of the aorta, to the increased density of the vessel when radioscopically observed. They state that deposits in and increased thickness of the aortic walls, as well as the greater volume of the liquid column, intensify the density of the aorta. They refer to a case of Brodin and Ronneaux, where a dense rounded patch was present at the origin of the ascending aorta. A necropsy proved this to be a small pocket covered with atheromatous plaques. They also mention that in some emphysematous subjects the pulmonary artery may be increased in density because it is atheromatous, whilst the aorta is free of this. In such cases the pulmonary artery is increased in density and the aorta is not.

A CASE OF CALCIFICATION OF THE ABDOMINAL AORTA.

A woman of 58 was referred to me for an abdominal examination. She complained of a weak digestion.

For three years she had pain in the back and epigastrium. and some degree of flatulence. There had been no vomiting, except 20 years before. She gave some vague symptoms of a "lump" in the epigastrium, and a previous history of bilious attacks accompanied by headaches. Recently, there had been constipation, and a loss of weight amounting to one stone in the last three months. She was of an active disposition, and looked pale. The X ray examination previous to the opaque meal showed an enlarged gall-bladder and a large shadow, perhaps a gall-stone. The gastro-intestinal tract showed no abnormality. Subsequently a cholecystogram established the diagnosis of an abnormal gall-bladder and the presence of a large gall-stone. This was confirmed at the operation.

In an attempt at diagnosis on the first examination a lateral view was secured to show the position of the probable gall-stone in relation to the anterior abdominal wall, and also that of a rounded calcareous body on the left side. It was then noticed that there was a dense straight column of calcification in front of the lumbar spine. A further study of other films showed two parallel lines over the spine, and it was then that extensive calcification of the abdominal aorta was diagnosed (Fig. I.). The systolic blood pressure was 160 mm. A faint systolic murmur was heard at the cardiac apex; there was no albumin in the urine. At the operation the aorta could not be felt, probably because of lack of pulsation. The patient made a good recovery.

Clinical symptoms of this severe atheroma were absent, and in all probability such extensive calcification of the abdominal aorta would have been totally unsuspected had it not been for the lateral examination of the abdomen. Lines of calcium of varying length in a single line in front of the lumbar spine had several times come under my observation, but this example showed the extreme degree which it could reach. It is interesting that such an amount of degeneration should not produce symptoms, but a vessel with a large lumen like the abdominal aorta may be calcified without much narrowing, or the lumen may be ample for a proper supply of blood to its territory. In a small artery or a terminal one, the calcification, if accompanied by narrowing, will more readily prejudice the blood-supply of an organ like the heart. Atheromatous changes in elderly people may cause pain in the calves after walking a short distance, and radiological investigation reveals lime deposits in the vessels (Fig. II.).

THE USE OF OPAQUE INJECTIONS.

Can X rays reveal the presence of calcification of the coronaries, or will narrowing of their vessels ever be shown radiologically? Is their detection possible by the recognition of calcified atheromatous plaques, or by the injection of opaque substances of the nature of uroselectan or abrodil? These questions lead to the consideration of lipiodol when injected in the blood-vessels, and to the position of the coronaries and the best way to observe them.

In Orrin's "Systemic Arteries" is to be found a lateral view of the dead fœtus showing all the vessels of the body injected. The radiogram was taken with the arms fully extended above the head. The right and left coronary arteries are seen. The left is placed well anteriorly and at no great distance from the posterior sternal surface. His primary object in demonstrating the vascular system by means of X ray was purely anatomical, and circumstances led him to use a fœtus.

Sicard and Forestier showed that it is possible to inject lipiodol into vessels and to follow its dissemination in the circulation by radioscopy and radiography. Brooks, in 1924, exposed the femoral artery under a local anæsthetic, having placed a tourniquet around the thigh, and injected into the artery 10 c.cm. of concentrated sodium iodide solution. Severe arterial pain followed the injection. Harvier and Lemaire evidence of nucleoli could be made out. Large and small cells seemed to be present in approximately equal numbers.

Urine.—Alkaline. Heavy deposit of amorphous phosphates. A few epithelial cells and an occasional leucocyte were found. No albumin, red cells, casts, abnormal crystals, or bacteria were found.

Histological examination of a section of skin removed from one of the largest nodules on the right leg at the upper *margin of the affected area (see Fig. 2)* showed a diffuse infiltration with lymphocytes of the deeper layer of the cutis vera. The papillary layer and the epidermis were not affected. No plasma cells or endothelial cells were seen, and neither fibroblastic reaction nor caseation was discovered (Fig. 3).

DISCUSSION.

From the dermatological standpoint the differential diagnosis appeared to lie between one of the rarer types of lichen planus, a syphilitic manifestation, and the rare but well-recognised condition of leukæmia infiltration of the skin. In view of the concurrent evidences of syphilis and leukæmia, a histological examination of the skin was necessary. The findings appear to point definitely to a leukæmic origin of the skin lesions, for if they had been gummatous not only would ulceration have taken place earlier in the course of the disease, but, histologically, there would almost certainly have been evidences of plasma cell infiltration and caseation.

Our reason for publishing this case is that skin lesions in lymphatic leukæmia are very seldom seen; when they do occur they are usually of secondary importance, for they commonly develop after the diagnosis is established, whereas in this case the skin lesions afforded the earliest and the chief source of the patient's anxiety.

Our thanks are due to Dr. Goldsmith for referring the case to us individually, and to Dr. L. S. Ashcroft, of Liverpool, for making the preliminary examination when the patient was in hospital.

THE ÆTIOLOGY AND TREATMENT OF ANÆMIA IN PREGNANCY.*

BY MAURICE B. STRAUSS, M.D.,

AND WILLIAM B. CASTLE, M.D.

THE "physiologic" anæmia of pregnancy was investigated by studying the blood, the gastric secretions, and the dietary histories of a group of normal women throughout pregnancy. More than half of these women showed a marked decrease or absence of free hydrochloric acid in the gastric juice during pregnancy, with a return to normal following parturition. These women, and those with poor diets, had an average loss of 12 per cent. hæmoglobin during pregnancy, whereas women who showed a less marked decrease in free hydrochloric acid and who ate satisfactorily during pregnancy lost an average of only 5 per cent. hæmoglobin. Three women with permanent post-histamine gastric anacidity had an average loss of 18 per cent. hæmoglobin in spite of their satisfactory dietary intake during pregnancy. These observations indicate the importance of direct dietary deficiency and deficiency conditioned by changes in the gastric juice in the ætiology of the "physiologic" anæmia of pregnancy.

Thirty-five women who had less than 45 per cent. hæmoglobin during the latter half of pregnancy or following parturition were studied. Nineteen of these were found to have post-histamine gastric anacidity and 12 more had little or no free hydrochloric acid following alcohol test-meals. In addition to this striking incidence of disturbed gastric function, over two-thirds of these patients were found to have had diets which were definitely deficient in iron and other mineral elements and in protein.

None of the 35 patients made any significant improvement during control periods without therapy. Thirty had anæmia of the hypochromic type. Liver extract produced no improvement in these cases; but all treated with large doses of iron improved rapidly, gaining an average of 0·65 per cent. hæmoglobin per day—whether treated during or after pregnancy.

The observations on the hypochromic anæmia of pregnancy correspond to similar studies on idiopathic hypochromic anæmia and indicate that the ætiologic factors of direct dietary deficiency and deficiency conditioned by gastric anacidity are common to both. Furthermore, an analogy may be made between the blood requirements of the fœtus and the chronic blood loss associated with certain cases of idiopathic hypochromic anæmia. In addition, the therapeutic value of iron is shown to be as great in the hypochromic anæmia of pregnancy as in other hypochromic anæmia.

Five patients had anæmia of the hyperchromic type (pernicious anæmia of pregnancy). Two of these became well under therapy with iron and two under therapy with liver extract. In view of the observations previously made upon Addisonian pernicious anæmia, the effect of beefsteak and gastric juice was studied. Beefsteak alone was found to have no effect upon blood formation upon one patient with macrocytic anæmia during pregnancy and to have distinct effect after parturition. Immediately thereafter beefsteak plus normal human gastric juice was found to have a markedly positive effect. Since patients with "pernicious anæmia of pregnancy" remain well once cured, it is reasonable to believe in the light of these observations that the anæmia is due to the temporary loss of the intrinsic factor of the gastric juice during pregnancy with an ultimate return occurring sooner or later after delivery.

The observations on the hyperchromic anæmia of pregnancy indicate that in addition to an iron deficiency in most cases, there is a temporary absence from the gastric secretions of the specific intrinsic factor, the complete absence of which has been invariably observed in Addisonian pernicious anæmia in relapse.

Hence the same ætiologic mechanisms hold for the anæmias of pregnancy as for similar anæmias in non-pregnant individuals, and like therapy is equally efficacious.

---

*THE ÆTIOLOGY AND TREATMENT OF SPRUE IN PORTO RICO.**

BY WILLIAM B. CASTLE, M.D.,

AND CORNELIUS P. RHOADS, M.D.

STUDY of 100 cases of sprue in Porto Rico, including cases in all stages of the disease, demonstrates a close relationship between this disease and Addisonian ernicious anæmia as to ætiology and the most atisfactory methods of treatment. As has been postulated for pernicious anæmia by one of us W. B. C.), three possible mechanisms or combinations of these may be involved in the production of the "conditioned deficiency" believed to be the immediate cause of pernicious anæmia. Free hydrochloric acid was demonstrated after an alcohol test-meal in the gastric contents of about half the cases examined; after histamine, in about 20 per cent. more. In certain cases of sprue a lack of "extrinsic factor" in the diet, or a lack of "intrinsic factor" in the gastric juice, both in early and late stages of the disease, was demonstrated. In some advanced cases an apparent difficulty in the absorption of hæmopoietic substances from the gastro-intestinal tract was found to be an additional factor conditioning the major deficiency. The deficient substance is apparently identical with the hæmopoietic substance produced by the interaction of beef muscle and normal human gastric juice or with the extracts of liver described by Cohn, Minot, and their collaborators as effective in pernicious anæmia. The sternal bone-marrows examined after biopsy before treatment showed a megaloblastic proliferation comparable to that seen in pernicious anæmia. No evidence of aplasia was obtained. No significant correlation between *Monilia psilosis* infection and sprue was observed in cultures of the stools of various types of anæmia.

---

* Abstra[illegible] made to the American Society for Clinic[illegible] 2nd. From the Thorndike Memorial [illegible] ical Services (Harvard) of the Bostor [illegible] Department of Medicine of the Harva[illegible] n.

* *Abstract of a communication* made to the Association of American Physicians on May 4th. This work was done in Porto Rico under the auspices of the Rockefeller Foundation in collaboration with Dr. George C. Payne and in coöperation with the Thorndike Memorial Laboratory *of the Boston City* Hospital and the Departments of Medicine and of Tropical Medicine of the Harvard Medical School.

In nearly all the cases of sprue prompt symptomatic relief of sore tongue and diarrhœa was obtained from the administration of the liver extract effective in pernicious anæmia, either orally or especially by parenteral injection. The latter procedure was positively life-saving in a few cases and the cost of treatment materially less. In those cases with a hyperchromic blood picture adequate dosage with liver extract alone produced reticulocyte crises and improvement of the blood values occasionally as striking as in pernicious anæmia but usually of a decidedly modified character. In many cases satisfactory progress was not made without the addition of iron ammonium citrate, especially when, after treatment with liver extract, the hyperchromic anæmia became hypochromic in character. In a small number of cases of sprue with an original hypochromic blood picture iron therapy was effective in relieving the anæmia, but not the gastro-intestinal symptoms which, however, yielded promptly to liver extract. In a few cases autolysed yeast preparations produced reticulocyte crises and improvement of the blood values.

MEDICAL SOCIETIES

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

At a meeting of this society held on May 27th, Mr. DAVID LEES presiding, Mr. H. E. MELVILLE (National Provident Insurance Society) opened a discussion on the

Attitude of Life Insurance Societies to Venereal Disease.

He said that an actuary had the responsibility of deciding whether a proposal for insurance should be accepted at the ordinary rate, or at a special premium. To guide him in the decision he had the statements of the medical officer, and whatever statistics were available on the point. The actuary was always thinking in terms of averages, on which the whole principle of life assurance was based. An individual, accordingly, was but one of a group. To be eligible for ordinary rates, the applicant must be physically fit and free from disease at the time, and there must be nothing in his occupation, surroundings, family history, or personal history or mode of life to suggest anything in the nature of an extra hazard. The mode of life could be defined as the moral hazard, a factor always present in the actuary's mind when the insuree had had venereal disease, for it was a question whether health had been deteriorated. Having had such a disease, especially if he had had a venereal disease more than once, he must be regarded as an intemperate person, and so would be charged an extra premium. He asked whether a group of men who had had venereal disease would show a heavier mortality than a group similar in all respects except that they had not had venereal disease. If so, what was the difference? Also, did the extra mortality come early or late in life? Was it related to the man's age or the duration of time since he became infected? Actuaries knew but little about these factors, and statistics available did not help. His office dealt with cases of gonorrhœa and syphilis respectively according to the following general principles.

Gonorrhœa.—If the applicant had had repeated attacks of gonorrhœa, even if each attack had been cured, he was charged extra. If he had had only one attack and had been cured, and the life otherwise seemed ordinary, the ordinary rates would apply. A different attitude was taken if the gonorrhœa had left a stricture; if the stricture had not been cured the proposer would either be regarded as not insurable or he would be definitely loaded; some offices loaded the premium if the stricture had been treated.

Syphilis.—The many statistics gathered on the subject showed a heavy mortality among those who had had syphilis. Scandinavian statistics showed an incidence and a mortality lighter at the middle ages than at the older ages. It was difficult to get the facts about syphilis; often one had to rely on the proposer's own statements. In an important case it was worth spending money to get information from experts, but that was only possible when the person had been recently treated. The office was therefore compelled to lay down certain rules. These were: No syphilitic proposer should be accepted for insurance unless he were (1) thoroughly treated to the best of present knowledge; (2) several years had elapsed from the date of infection and treatment, and no symptoms had developed in the meantime; (3) the proposer's physical condition, family history, and habits were satisfactory. Even should these conditions be complied with, ordinary terms would not be granted. His office considered that if a man acquired syphilis at 40 years of age or over, he was a worse risk than if he were younger when he became infected. He asked what medical justification there was for this impression. The Royal Commission on Venereal Disease had recommended confidential certification of the causes of death; but life offices would oppose anything of that kind. Anything which would prevent disclosure of cause of death would encourage fraud.

Dr. OTTO MAY said that in a proper life assurance office the function of the actuary and that of the medical officer should be complementary to each other. For a sound judgment it was necessary for the actuary to have a series of groups of people all suffering from one impairment; for example, one group of those who had suffered from primary chancre and had radical treatment, with no further developments; a group of patients whose treatment had only begun in the secondary stage; and a further group among whom tertiary manifestations were observed. The chief function of medical examiners should be, not to assess the risk, but to tell the actuary into which group an individual case should be placed. That, however, was an ideal which could not be followed; there was not enough material available in the shape of uncomplicated cases. In practice people who had venereal disease were often accepted at ordinary risks, because it was not known who had had syphilis; the ordinary form did not ask about venereal diseases, and a proposer would scarcely volunteer that he had had syphilis. But the medical form asked the question, and a few who had had syphilis admitted it, perhaps less than 1 per cent.; if it were true that 10 per cent. of the population had had the disease at some time, the commentary was obvious. He dissented from the idea that because a man had had venereal disease he was necessarily a libertine. Dr. May suggested that the interval after infection at which general paralysis supervened was mostly about ten years. The extra mortality from tabes he regarded as comparatively insignificant. A further question to be considered was the maximum incidence of the various forms of aortic disease and myocardial disease which were attributable to syphilis. The insurance office did not want to know what a man would die of after syphilis, but after what interval, in what numbers, and at what ages, and also what effect syphilis had on mortality in various groups. It was open to doubt whether modern treatment of syphilis was altogether an advantage, since the energetic and long-continued courses now declared to be necessary might possibly impair the vitality of the essential organs of the body. One heard of 30 to 40 injections, after the Wassermann was negative, of a substance generally regarded as a protoplasmic poison. Sir Jonathan Hutchinson had taken a favourable view of the outlook for a syphilitic subjected to the treatment formerly considered best. Sir Jonathan had declared he would like to run an insurance company entirely for syphilitics, as it would make a good profit, seeing that a syphilitic would henceforth live a very careful life. Dr. May favoured the disregard of gonorrhœa which had been cured. He had never suggested rating a man up for what was called a moral hazard, but recurrent gonorrhœa, as well as a gonorrhœal stricture, led to the loading of a policy.

Mr. Robert Cubie (National Mutual Life Assurance Company of Australia) said his office took no particular account of gonorrhœa. The influence of syphilis was held to be greater in the later years of life than in the middle years. If no specialist report of the case could be procured a proposal from a syphilitic was not considered at all. If treatment had been thorough, and cure had probably ensued, importance was attached to the family history.

Dr. H. M. Hanschell said that the assumption that syphilologists were agreed on what constituted adequate treatment was untenable. There had not yet been a sufficient interval of time since modern treatment was instituted, nor enough following up of cases to enable the profession to be certain what happened. Though Sir Jonathan Hutchinson remained an optimist, usually the older generation of medical men were pessimistic about syphilis.

Lieut.-Colonel L. W. Harrison suggested that a proposer who confessedly had had syphilis and had been well treated should be accepted at a lower premium than the average. The general population contained a very large number of undeclared syphilitics. He was not a pessimist, having encountered many patients who, after treatment, had remained Wassermann negative for six or more years. Wassermann seldom became positive again after such an interval. Life assurance offices, working on mass principles, often loaded a case too heavily for syphilis. He thought that life assurance offices would be better advised, and would have more proposals if they were to pay attention to the amount of treatment the proposer had received if he had had syphilis. He was not aware that serious damage to the liver had resulted from the use of arsenical preparations.

Dr. Claude Mills thought that if insurance people took into account the factors Colonel Harrison mentioned, the syphilitic, dealt with as an individual and not as a member of a group, would oftener get a fair deal. The question about syphilis should be put by the medical examiner; the proposer should not be required to enter the answer on a form. If a man had been infected with syphilis fairly young, mortality was likely to occur at about 50 years of age. In females, it was agreed, syphilis was a much milder disease than in males.

Dr. Buckley Sharp said that most patients with syphilis discontinued treatment too soon and they could rarely be followed up closely enough to determine whether they were cured. For these reasons he never recommended the acceptance of a syphilitic patient at ordinary rates. Gonorrhœa was often recorded on the form returned by patients. A stricture might not declare itself for some years, but if adequate skilled treatment had been received and the urethroscope revealed nothing abnormal, he saw no reason against acceptance at ordinary rates. There was no absolute criterion of cure of syphilis; a sequel at 50 to 60 years of age might be myocarditis, with aortic regurgitation, and no treatment could restore the damaged valves to the normal. The average period after infection for the onset of G.P.I. was 13 years. These disasters were most likely in cases which had only been partially treated.

Dr. F. C. Doble said he would not load a proposer for syphilis if he had been properly treated and tested, nor for a history of gonorrhœa if he were found free from it. Information on venereal disease was best extracted diplomatically by the doctor, rather than asked for on the form.

The President said that the time was now ripe for syphilologists to give the lead to those responsible for advising actuaries of life assurance societies. It was unfortunate that at present they were being advised by physicians who were not constantly handling syphilitic cases.

A certain percentage of male prostitutes were constantly getting venereal disease, and doctors could do a good work by impressing on them the need of abstinence. The matter could not be dealt with from the mass point of view; it was unfair to load a patient who had had syphilis but was now sero-negative and cured. He thought life insurance people laid too much stress on the family. The main points to consider in life insurance were, the amount and kind of treatment the patient had had, and the stage of his disease at which it was carried out. For five years search had been made in the post-mortem room of Edinburgh Royal Infirmary for cases of lamaged liver following arsenical treatment for yphilis without finding one. He felt sure that neuro-ecurrence was very much rarer than was generally upposed; he had encountered only one case of it in 12 years. That showed that modern treatment was achieving something. He felt that insurance offices were still being guided by the advice of the physicians who practised 25 or 30 years ago.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OBSTETRICS AND GYNÆCOLOGY.

At a meeting of this section held on May 20th a discussion on

The Teaching of Obstetrics

was opened by Mr. **Eardley Holland**, who gave a résumé of the gradual evolution which had taken place in the teaching of obstetrics during the past 70 years. He said that perhaps the most significant event that had ever happened for obstetrics was the recent report of the Departmental Committee on Maternal Mortality and Morbidity. The committee considered the revised curriculum recommended by the General Medical Council, which came into operation in 1932, as a great improvement on all previous medical curricula officially recognised, but in their opinion it still fails to allow sufficient time and occasion for the adequate education of the student in practical obstetrics. They concur with the view expressed by the Royal Society of Medicine in 1919 that the practical instruction leaves much to be desired, and in some respects merits emphatic condemnation. This report was forwarded to the General Medical Council, but the licensing bodies were unable to agree to six months' exclusive instruction, nor to the number of cases of labour that were laid down as a minimum.

Mr. Holland then discussed the difficulties, maintaining that the inadequate number of beds was the chief among these. In his opinion the pooling of beds among the various teaching hospitals, and the formation of very large units of not less than 200 beds, was the only solution of the problem.

Mr. **Carnac Rivett** said that at the Middlesex Hospital the theoretical aspect of gynæcology and obstetrics was dealt with in the lectures delivered by the honorary obstetric surgeons during the summer session, and these were made as clinical as possible. In addition to this he, as obstetric tutor, held a revision class four times a year. Antenatal clinics also were held twice a week throughout the year, and were conducted by the two assistant obstetric surgeons. Although the material for antenatal examination was adequate, he pointed out the difficulty of getting sufficient material for actual confinements, particularly abnormal confinements. In the hospital they had 10 to 14 beds, which it was hoped would be increased to 40 when the rebuilding scheme was complete. They had an understanding with the Royal Northern Hospital that their students should go into residence, and should get their district cases in the north of London. At present the students only had one month's practical midwifery, but it was hoped in the near future to increase it to six weeks. He stated that he believed in assistant midwives for teaching normal delivery, and he did not think there was any objection in teaching students and midwives together, except that the midwives took cases which otherwise would be available for students. Referring to the question of abnormal deliveries, he said that for the average student experience in this part of the work was practically absent, and he saw no way of getting over this except by concentrating the cases into three or four large units in London, each consisting of 250 beds.

Dr. **Ninian Falkiner** (Rotunda, Dublin) said he felt strongly that it was not the introduction of new methods into clinical teaching, but the insistence on the residential system for students which would result in the diminution of the maternal mortality, the only real criterion of the efficiency of the teaching. He considered it advantageous to maintain systematic lectures in the university curriculum, in order that the student might know something of the groundwork before entering on his clinical experiences. He thought more stress should be placed on teaching the physiology of reproduction than had previously been done. He thought that it was of serious interest that the mortality in the districts run by the hospitals was so much below that of the general mortality throughout the country, and gave the possible explanation that while doctors are notoriously always in a hurry, students are hardly ever so pressed. He discussed the difficulty of getting sufficient abnormal cases to teach students even to use forceps, but did not at present see any solution. He agreed that the use of phantoms was of value, but did not meet the whole difficulty. He referred to the fact that obstetrics is taught under ideal conditions, but that the student was obliged to go out and practise in conditions which were far from ideal. He thought that more prizes should be offered to stimulate interest, and suggested that these should be given for the cytology of reproduction, the physiology of reproduction, the anatomy of the female pelvis, and the pathology of reproduction.

Mr. **A. C. Bell** (Queen Charlotte's) said he had obtained the views of recently qualified men, and that as a whole they believed that the knowledge of gynæcological conditions on leaving hospital was sufficient for ordinary practice, but in the case of obstetrics this was far from true. He thought that the theoretical teaching of both obstetrics and gynæcology was excellent, but that some time should be given to discussion on the subject of birth control, which would be one of the things most frequently asked of the doctor in practice. He thought that the system of instructing students in pelvic examination in out-patients was practically useless, and held this could be remedied by examinations in the theatre under an anæsthetic by all the clerks present. He thought no student should ever be allowed to conduct a case on the district before he had seen the procedure in hospital, but considered it very important to have a resident obstetric tutor. He did not see any way of overcoming the difficulty of providing sufficient abnormal cases for every student.

Miss **Gladys Hill** (Royal Free Hospital) gave the personal experiences and opinions of a number of students now graduated in medicine, and trained since the institution of the obstetrical and gynæcological unit of the Royal Free Hospital. She sent out a questionnaire and analysed some 96 replies. One hundred per cent. agreed as to the importance of district maternity work; on the question of set lectures, a very small minority derived any benefit at all. Two-thirds of those answering the questionnaire were in favour of demonstrations with phantoms and models, and all were agreed as to the importance of labour ward teaching and antenatal clinics and tutorials.

other. For a sound judgment it was necessary for the actuary to have a series of groups of people all suffering from one impairment; for example, one group of those who had suffered from primary chancre and had radical treatment, with no further developments; a group of patients whose treatment had only begun in the secondary stage; and a further group among whom tertiary manifestations were observed. The chief function of medical examiners should be, not to assess the risk, but to tell the actuary into which group an individual case should be placed. That, however, was an ideal which could not be followed; there was not enough material available in the shape of uncomplicated cases. In practice people who had venereal disease were often accepted at ordinary risks, because it was not known who had had syphilis; the ordinary form did not ask about venereal diseases, and a proposer would scarcely volunteer that he had had syphilis. But the medical form asked the question, and a few who had had syphilis admitted it, perhaps less than 1 per cent.; if it were true that 10 per cent. of the population had had the disease at some time, the commentary was obvious. He dissented from the idea that because a man had had venereal disease he was necessarily a libertine. Dr. May suggested that the interval after infection at which general paralysis supervened was mostly about ten years. The extra mortality from tabes he regarded as comparatively insignificant. A further question to be considered was the maximum incidence of the various forms of aortic disease and myocardial disease which were attributable to syphilis. The insurance office did not want to know what a man would die of after syphilis, but after what interval, in what numbers, and at what ages, and also what effect syphilis had on mortality in various groups. It was open to doubt whether modern treatment of syphilis was altogether an advantage, since the energetic and long-continued courses now declared to be necessary might possibly impair the vitality of the essential organs of the body. One heard of 30 to 40 injections, after the Wassermann was negative, of a substance generally regarded as a protoplasmic poison. Sir Jonathan Hutchinson had taken a favourable view of the outlook for a syphilitic subjected to the treatment formerly considered best. Sir Jonathan had declared he would like to run an insurance company entirely for syphilitics, as it would make a good profit, seeing that a syphilitic would henceforth live a very careful life. Dr. May favoured the disregard of gonorrhœa which had been cured. He had never suggested rating a man up for what was called a moral hazard, but recurrent gonorrhœa, as well as a gonorrhœal stricture, led to the loading of a policy.

Mr. Robert Cubie (National Mutual Life Assurance Company of Australia) said his office took no particular account of gonorrhœa. The influence of syphilis was held to be greater in the later years of life than in the middle years. If no specialist report of the case could be procured a proposal from a syphilitic was not considered at all. If treatment had been thorough, and cure had probably ensued, importance was attached to the family history.

Dr. H. M. Hanschell said that the assumption that syphilologists were agreed on what constituted adequate treatment was untenable. There had not yet been a sufficient interval of time since modern treatment was instituted, nor enough following up of cases to enable the profession to be certain what happened. Though Sir Jonathan Hutchinson remained an optimist, usually the older generation of medical men were pessimistic about syphilis.

Lieut.-Colonel L. W. Harrison suggested that a proposer who confessedly had had syphilis and had been well treated should be accepted at a lower premium than the average. The general population contained a very large number of undeclared syphilitics. He was not a pessimist, having encountered many patients who, after treatment, had remained Wassermann negative for six or more years. Wassermann seldom became positive again after such an interval. Life assurance offices, working on mass principles, often loaded a case too heavily for syphilis. He thought that life assurance offices would be better advised, and would have more proposals if they were to pay attention to the amount of treatment the proposer had received if he had had syphilis. He was not aware that serious damage to the liver had resulted from the use of arsenical preparations.

Dr. Claude Mills thought that if insurance people took into account the factors Colonel Harrison mentioned, the syphilitic, dealt with as an individual and not as a member of a group, would oftener get a fair deal. The question about syphilis should be put by the medical examiner; the proposer should not be required to enter the answer on a form. If a man had been infected with syphilis fairly young, mortality was likely to occur at about 50 years of age. In females, it was agreed, syphilis was a much milder disease than in males.

Dr. Buckley Sharp said that most patients with syphilis discontinued treatment too soon and they could rarely be followed up closely enough to determine whether they were cured. For these reasons he never recommended the acceptance of a syphilitic patient at ordinary rates. Gonorrhœa was often recorded on the form returned by patients. A stricture might not declare itself for some years, but if adequate skilled treatment had been received and the urethroscope revealed nothing abnormal, he saw no reason against acceptance at ordinary rates. There was no absolute criterion of cure of syphilis; a sequel at 50 to 60 years of age might be myocarditis, with aortic regurgitation, and no treatment could restore the damaged valves to the normal. The average period after infection for the onset of G.P.I. was 13 years. These disasters were most likely in cases which had only been partially treated.

Dr. F. C. Doble said he would not load a proposer for syphilis if he had been properly treated and tested, nor for a history of gonorrhœa if he were found free from it. Information on venereal disease was best extracted diplomatically by the doctor, rather than asked for on the form.

The President said that the time was now ripe for syphilologists to give the lead to those responsible for advising actuaries of life assurance societies. It was unfortunate that at present they were being advised by physicians who were not constantly handling syphilitic cases.

A certain percentage of male prostitutes were constantly getting venereal disease, and doctors could do a good work by impressing on them the need of abstinence. The matter could not be dealt with from the mass point of view; it was unfair to load a patient who had had syphilis but was now sero-negative and cured. He thought life insurance people laid too much stress on the family. The main points to consider in life insurance were, the amount and kind of treatment the patient had had, and the stage of his disease at which it was carried out. REVIEWS AND NOTICES OF BOOKS

ital Records in the Tropics.

By P. GRANVILLE EDGE, Division of Epidemiology and Vital Statistics, London School of Hygiene and Tropical Medicine. London: George Routledge and Sons, Ltd. 1932. Pp. 167. 7*s*. 6*d*.

Major Edge, in collaboration with Prof. Major reenwood, was responsible for many of the very iluable handbooks on the vital statistical systems European countries published by the League of ations. His detailed knowledge of these registration stems, in conjunction with his experience of tropical nditions, therefore, makes him an eminently itable guide to those who are concerned with the lection of systems suitable to tropical dependencies, here the collection of accurate statistics is a task hich has hardly been seriously undertaken. Three apters of the book are devoted to census taking, e details usually required, e.g., sex and approximate ;e. and the possible methods of securing them, and ur chapters to systems of registration of births, eaths, and diseases. Major Edge sets out clearly e ideal which officials should have before them, lding that they must not be discouraged if only two three facts are actually recorded in the early ages of a scheme. That reliable vital statistics ill never eventually be secured he refuses to believe. bviously, as he points out, no hard-and-fast scheme n be laid down; much of it must depend upon cal conditions, which only the worker on the spot n assess. The value of these chapters lies in the ear outline they put before the local official of the ata he must aim at, and in the author's enthusiasm r accurate statistics, some of which will, doubtless, e imparted to the reader. The collection of records hich are immediately labelled unreliable, as is so ften the case at the present time, is mere waste of ime, energy, and money; an inquiry even on the mallest scale with accurate results would be more atisfactory and infinitely more so if it were likely to e the precursor of more comprehensive statistics.

The latter half of the book is devoted to the rinciples of the tabulation of data and their graphical epresentation; and to the computation of simple ates. It contains only matter with which every ompiler of an official health report should be familiar. t might even be considered too elementary if it ere not for the gross elementary errors which actual ublished reports not infrequently contain—e.g., he addition and averaging of rates based upon opulations of widely varying size. A few hours' tudy of it will enable the medical officer to avoid ot only such errors, but the drawing of erroneous onclusions from crude birth- and death-rates.

Thrombose.

Ihre Grundlagen und ihre Bedeutung. By Prof. Dr. A. DIETRICH, Director of Pathological Institute, University of Tübingen. Berlin: Julius Springer. 1932. Pp. 102. R.M.S.80.

THIS, the fourth volume of a special pathological and clinical series emanating from Central Europe, provides an authoritative account of the pathology of thrombosis in the classical German style. His extensive experience of thrombosis as a complication of war wounds, as well as his own experimental observations, have led Prof. Dietrich to ascribe to infection the chief rôle in this process, although he readily admits the importance of other factors such as circulatory disturbances, injury to the vessel walls, and alterations in the electrical charge on the blood-platelets. The latter factors are, however, in his opinion, of subsidiary importance. The mechanism of the infective process is explained as an interaction between the vessel wall, especially the endothelium, and the fluid blood. This interaction is brought about by a sensitisation of the animal to foreign substances, whether these be bacteria or proteins. Protocols, illustrated clearly by a number of microphotographs, are given of some of the experiments upon which this theory is based. These represent an important contribution to the study of thrombosis and merit close attention. The theory offers an explanation of the occurrence of thrombosis at sites remote from the infective focus. Yet the fact that there are sites of predilection for thrombosis, for example in the upper part of the femoral vein, indicates that a static factor is also involved in the process. As Aschoff has said, the process is too complicated to justify its reference to any single factor or cause. It is a pity that the bibliography is incomplete; in all other respects the book will be found most useful by students of the subject.

Nutritional Physiology.

Seventh edition. By PERCY GOLDTHWAIT STILES, Assistant Professor of Physiology in Harvard University. London: W. B. Saunders Co., Ltd. 1931. Pp. 313. 10*s*. 6*d*.

IN this small manual Prof. Stiles explains in simple terms the mechanism of digestion and of the metabolism of foodstuffs. The keynote of the exposition is the energy exchange of the human body, and the modern conception of the immense importance of minute qualitative changes in a diet is not stressed even in this latest edition. Chapters are included which have no immediate bearing on nutritional problems, such as those describing the circulation, the nervous system, and the glands of internal secretion. The reader is warned in the preface that the book should be read in conjunction with manuals on such subjects as food chemistry and dietetics, and it must be regarded as an elementary outline of certain aspects of physiology rather than a study of nutrition.

The Foundations of Medical History.

By Sir D'ARCY POWER. London: Baillière, Tindall and Cox. Pp. 182. 16*s*.

THE Institute of the History of Medicine attached to the Johns Hopkins University invited Sir D'Arcy Power recently to deliver a series of lectures on medical history, and this little volume is the interesting and amusing result. Starting loyally with the history of his own, St. Bartholomew's Hospital, Sir D'Arcy abruptly turns to dietetics and gives a very lively description of dinner-table habits in Egypt, Greece, and Rome, and especially in mediæval England. He believes the prevalent moderation, to be seen in public gatherings as well as at the private board, must be having a real influence on longevity. There are three chapters respectively on biography, iconography, and bibliography in which the author displays an intimate knowledge of great men's lives, their appearance, and the manner in which

Dr. W. J. H. M. BEATTIE thought that the continental system of having one or more very large obstetric clinics in each city to which successive batches of students should go and live for a period was better than the method adopted in this country. Dr. Beattie's post at St. Bartholomew's Hospital of resident assistant physician accoucheur embraced the post of resident obstetric tutor. Among his duties was to give tutorial classes and practical demonstrations, which had the advantage over set lectures that the student is at liberty to ask for information when he does not understand any particular point; but too much attention was paid to the theoretical and purely academical side of teaching, owing no doubt to anxiety that the student should pass his qualifying examination. This evil was brought about by the examiners in obstetrics and gynæcology asking certain questions on ætiology and other matters which are still controversial. He thought that the physiology of reproduction was sufficiently dealt with, and doubted if more detailed instruction would be of any value. He had circularised many of the senior students at St. Bartholomew's Hospital, and found that they considered there was insufficient obstetrical material, especially from the point of abnormal labour. Most students agreed that a longer period of time should be devoted to the study of obstetrics, and possibly less time for gynæcology, which at present extends over three months. He finally stated that he thought the more generalised post-graduate teaching in gynæcology and obstetrics would be an important factor in the better education of the recently qualified man.

Mr. W. G. MACKAY (Glasgow Maternity Hospital) said that much progress and improvement had taken place in the teaching of obstetrics in Glasgow of recent years, under the far-sighted direction of Prof. Munro Kerr. He agreed with a great deal that the previous speakers had said, and in discussing the difficulty of finding material for obstetrical operations, he maintained that the great thing was to devote much time to the simple operations which every doctor should be capable of performing, but not to worry at all about the more difficult operations which require the services of a specialist. He contended that one of the mistakes at present being made was that the final examinations were not sufficiently clinical in character.

Mr. A. J. WRIGLEY (St. Thomas's Hospital) based his paper on the results of a questionnaire from over 20 friends in practice, and criticised severely the present methods of teaching, especially the fact that the student was taught to treat obstetrical cases as if all his work was going to be in an institution or a nursing home. He thought that an undue proportion of the time of the student was spent in the surgical wards, whereas in practice the young qualified doctor would be concerned much more with midwifery.

Mr. J. B. BLAIKLEY (Guy's Hospital) said that, whereas lectures are necessary in teaching, the practical work in the labour room and wards is of prime importance; lectures should be kept to the minimum necessary to form a groundwork of understanding on which the student may build. It is important to live at least three months sufficiently close to the hospital to see the abnormal midwifery dealt with during that period. A student cannot be made into a complete obstetrician, and be allowed to practise with forceps and undertake such obstetric manœuvres as internal version; it is only after qualification that it is really possible for this to be done, when a man is sufficiently in touch with his patients to learn for himself. He thought that with the great amount of obstetrics practised in the municipal hospitals of London, it might be possible, by suitable arrangements, for many more men to obtain experience in obstetrics subsequent to qualification than at present. Examinations should be kept as practical as possible for that reason. At Guy's they were, he said, unfortunate in that the men take "conjoint" pathology in the middle of their obstetric appointment, and this interferes with the attention they devote to midwifery. Mr. Eardley Holland had referred to "an absence of any resident post between house surgeon and the staff"; at Guy's the registrar is resident or lives within a few minutes—also the assistant surgeon. Mr. Blaikley was opposed to the teaching of medical students by the ward sister. An obstetric resident (house surgeon) was, he held, quite competent to teach normal labour if well taught himself; this was the custom at Guy's, where a member of the staff or the registrar was always present for any obstetric interference, and took the opportunity to teach on the case at the time. Mr. Blaikley concluded as follows: "I would differ from those who find 20 or 24 beds too few for teaching purposes; when a fair percentage of emergency cases are admitted, they seem to me sufficient. It is no more possible to learn obstetrics than a handicraft except by apprenticeship, which implies learning by personal experience. Previous to qualification, no more than a sound groundwork for future building can be grasped by a student."

Mr. R. A. BREWS (London Hospital) explained in detail the curriculum. He stated that he thought the frequent change of students made it very difficult to prevent or detect a tendency to slacking in certain individuals. He found that a great many students were reading medicine and surgery when they were supposed to be learning midwifery.

Mr. J. C. MOIR (University College Hospital) said that he believed in the phantom as an aid to teaching, and thought that the systematic lectures would be improved if they were given to students who were at the same stage in their curriculum. It was impossible to give a satisfactory lecture to students, some of whom knew nothing of the subject, and others who were almost ready to qualify.

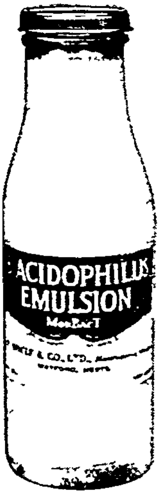
Miss K. I. PARKES (King's College Hospital) advised more care over the teaching of venereal disease in gynæcology. She rather advocated two courses of obstetrical teaching, one for those who really were going to practise it, and a modified course for those who were merely qualifying in taking up other subjects, such as dentistry.

Mr. C. D. READ (Westminster Hospital) had collected the ideas from a representative body of senior students and newly qualified practitioners, and came to the conclusion that insufficient detail was given on the question of antisepsis under adverse surroundings, such as attended a confinement in the slums. Forceps application is taught almost entirely on the dummy, and he thought more practice might be obtained in actual hospital deliveries. The question of anæsthesia during labour, so necessary in private practice, is only meagrely dealt with. Over 90 per cent. of the cases delivered in the hospital are book cases, and therefore the delivery is normal. He thought that more prominence should be given to the normality of labour and its physiological principles, and more stress should be placed on the danger of unnecessary interference in any way.

EMULSION

ACTOBACILLUS ACIDOPHILUS

(Minimum Count: 250 Million per c.c.)



Weekly examinations of the fæces will disclose the rapidity with which the intestinal flora is affected by the large quantities of viable B. Acidophilus incorporated in this very palatable emulsion

B. ACIDOPHILUS EMULSION

overcomes toxæmia of intestinal origin and promotes adequate defæcation. *12 oz. Bottles 7/6.*

and know that you are doing the best possible for your patients.

history has treated them. He closes with a little notice of "Aristotle's Masterpiece," that queer book which, under various titles, used to be on display in the shop windows of the vendors of "rubber goods." One learns with some surprise that its contents, though having an appeal to the prurient, constitute an entertaining summary of mediæval superstitions, and an extraordinary compilation of sixteenth and seventeenth century knowledge. The number of editions is remarkable, and examples of some of them are rare. Specimens of nine editions are in the possession of Prof. E. B. Krumbhaar, professor of pathology in the University of Pennsylvania.

Italian Medicine.

By ARTURO CASTIGLIONI, M.D. New York: Paul B. Hoeber Inc. 1932. Pp. 134. $1.50.

THIS small history of Italian medicine by Prof. Arturo Castiglioni, professor of medical history in the University of Padua, has been translated by Prof. E. B. Krumbhaar, the editor of the useful series published under the title of Clio Medica, who appears in the character of a bibliophile in the work reviewed above. The general claim of the author is that Italy has probably contributed more to the science of medicine in the past 1500 years than any other country in the world. With all allowance for patriotism this seems to be rather an exaggeration. The early labours of Italian anatomists form the main justification of the claim. It is true that the work of Italian surgeons, physicians, and researchers from the latter part of the nineteenth century up to to-day has often been new and of the highest value, but the field of medical science in Italy cannot fairly be described as having had the range attributed to it, and the fact that in a volume of 110 pages we do not reach the nineteenth century until the seventy-fourth page is significant. But Prof. Castiglioni has written a very readable little book in which the essential characteristics of Italian medicine are clearly set out.

Acute Otitis Media.

By W. MAYHEW MOLLISON, M.C.L., F.R.C.S., Surgeon in Charge, Ear and Throat Department, Guy's Hospital. Pocket Monographs Series. London: John Bale Sons and Danielsson. 1932. Pp. 71. 2*s*. 6*d*.

THE issue of this little pocket monograph is fully justified by the necessity of focusing attention on the dangers of acute otitis media, and on the need for perseverance in its treatment, since the prevention of a vast amount of deafness lies in the hands of the general practitioner. Mr. Mollison gives a concise but clear and well-balanced description of acute otitis, under the headings of subacute, or non-suppurative, and suppurative. Mastoiditis is included, as it is essentially a part of acute otitis, the successful treatment of which often involves opening the mastoid cells and antrum. A useful chapter is devoted to varieties of the disease: here, acute otitis as it occurs in infants, the septicæmic form of the disease, the variety due to the pneumococcus mucosus, and that occurring in some epidemics of influenza and associated with hæmorrhagic blebs on the drum, and external meatus are separately discussed. Mr. Mollison insists on the necessity of opening the mastoid in cases where suppuration has persisted for more than five or six weeks, even in the absence of all other symptoms. He advocates the use of drops of glycerinum acidi carbolici without specifying that they should be diluted, for the pharmacopœial drops are of the strength of 1 in 5, whereas the drops usually prescribed are not stronger than 1 in 20. No advice on local treatment of acute suppuration, after discharge has commenced, is offered; and the moot question of the use of dry dressings, drops, or lotions, is therefore not discussed. Interesting illustrative cases are given throughout. The index is quite inadequate, even for so small a book; for it contains but 35 names, and does not mention thrombosis or cerebral abscess.

Real Human Needs.

By R. MACNAIR, M.B., Ch.B. London: Williams and Norgate, Ltd. 1932. Pp. 250. 10*s*. 6*d*.

Dr. Macnair reinforces his straightforward thinking by copious quotations from some recognised authorities, and from some who cannot be regarded as such. He has produced a readable book upon religion, sex, and money in the light of modern thought. The criticism of religion amounts to finding the approaches of religion to vital problems unsatisfactory, whether they are regarded as a revelation based on history or as a code of morals. The author, citing many authorities, brings into juxtaposition various things that have happened or have been written with the idea of showing that the activities of true religion should concentrate upon the solution of the problems of to-day. The section entitled sex is divided into chapters dealing with the meaning of prudery and the functions and demands of sex; and again, while there is nothing new in the teaching, well-known views, truisms, and popular speculations are brought cleverly together, to end with a quotation stating "that the sexual act is not alone for 'the propagation of children.'" In the third section, which deals with money, the writer furnishes a summary of the existing economic system which appears to be a fair one, but the demand for the humanisation of economics requires more justification than has been put forward.

The author of this book has made full use of a wide range of reading. If the reading has left him uncritical as to the value of what the authors quoted have said, and as to the guarantee of authority that is afforded by their names, the attitude is not without its advantages. He has produced a suggestive and readable volume.

Sanitary Law in Question and Answer.

Third edition. By CHARLES PORTER, M.D., B.Sc., M.R.C.P. Edin., and JAMES FENTON, M.D., D.P.H. London: H. K. Lewis and Co. 1932. Pp. 220. 7*s*. 6*d*.

COMPILED by the medical officers of health for the boroughs of St. Marylebone and Kensington, this manual of sanitary law for the use of students of public health now appears in its third edition. The information appears to be remarkably complete and is contained in a small compass. The necessary use of abbreviations, which sometimes gives an algebraic appearance to the text of such summaries, is not overdone; the reader soon learns to know what kind of a L.A. is a C.C. or C.B.C., and what officers are S.I. or H.V. The presentation of facts in the form of question and answer is probably as good a method as any other when, as here, an adequate index is provided.

No student who masters this book need fear the examiner.

THE LANCET.

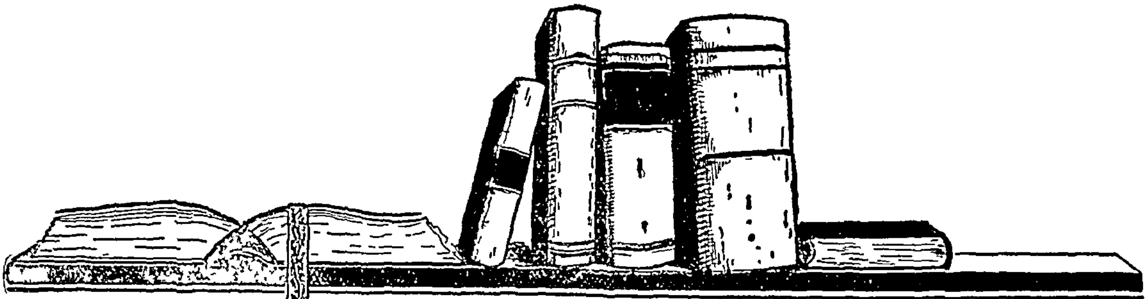
LONDON: SATURDAY, JUNE 4, 1932.

THE TEACHING OF OBSTETRICS.

THE Section of Obstetrics and Gynæcology of the Royal Society of Medicine held its annual "juniors' evening" on May 20th, when registrars and tutors from English, Scottish, and Irish schools gathered to discuss the subject selected for debate —on this occasion the teaching of obstetrics. To say that the discussion, which is reported on another page, was both interesting and instructive is an understatement; each of the younger members of the section stated his case with clarity and conciseness. So many wished to take part that the time-allowance had to be greatly restricted, but all managed to have their say with the minimum of bell-ringing. The views and ideals of those still in their apprenticeship as tutors have valuable lessons for those who have been teaching for many years; recently qualified men not only come fresh to the work but are in close contact with the student and are able to gather from him just where the shoe pinches. Admittedly the student still in hospital has somewhat obstructed vision; he cannot always see the practice of medicine for the examination that looms so large in the foreground of his prospect. But young obstetricians starting private practice have had to face the problem of adapting their institutional experience to the different conditions outside the hospital walls, and those who took part in the discussion were evidently imbued with a keen desire to give their pupils a better equipment for family practice. On the whole, the members of hospital staffs were treated tenderly by those preparing to step into their shoes, save for an occasional plaint that the visiting staff appeared too rarely in the labour room and left too much of the practical instruction to be given by inexperienced house officers. Some of the speakers had sent questionnaires to former students in order to determine which elements in the instruction customary at their school seemed, in the light of subsequent experience, to be useful, and which defective or superfluous. Systematic lectures, as contrasted with the more individual instruction of the tutorial or catechetical class were not favoured by those answering the questionnaires, and the speakers for the most part agreed with this view. It must not be forgotten however that tutorial classes may degenerate into mere spoon-feeding for examinations, and the fact that such instruction is greatly to the liking of the student would not necessarily be evidence in its favour were its value not confirmed by the response of the practitioners.

The shortage of clinical material, the relative infrequency of serious complications, and the haphazard occurrence of labour at all hours of the day and night, raise special difficulties in providing satisfactory training in the treatment of complicated labour that do not affect the teaching of gynæcology, or of the routine work of the antenatal clinic. Hence the discussion largely revolved round the question of the extent and type of the obstetric training to be given to the student who proposes to become a general practitioner. It was postulated that he could not be made into a skilled obstetrician capable of dealing with complicated midwifery. The most that time and opportunity permitted was that he should be turned out imbued with the principles of preventive medicine as exemplified in antenatal supervision; efficient in the management of normal labour and such emergencies as might arise unexpectedly in it; and familiar with the methods of applying the principles of surgical cleanliness in adverse surroundings and with the limitations of operative interference in domiciliary practice. Since instrumental deliveries are required in only a small proportion of hospital cases, which are largely "booked" cases, the occasions on which a student might be allowed an opportunity of applying the forceps under supervision are infrequent. Dr. **NINIAN FALKINER** called attention to the fact that the statistics from districts where the deliveries were carried out by students were more favourable than the general maternal mortality returns, and offered the explanation that while doctors are notoriously always in a hurry, the student is hardly ever so. He added that at the Rotunda Hospital the number of forceps-deliveries was far too small to permit every student to perform even one. The general acceptance of this position led up to various expressions of opinion on the value of teaching obstetric procedures on the phantom, to which were added complaints of the difficulty of obtaining stillborn fœtuses for this purpose owing to recent Government regulations. One speaker went so far as to urge that the student should not be taught any but minor procedures and those for unexpected emergencies, and that the major operations should not be made part of the ordinary training of the student. The necessity of at least two months' residence was strongly emphasised, whereas the actual number of cases to be personally delivered was little discussed and seems to have receded into the background. Certainly it does not now seem to be the burning question that it once was.

Much careful thought had obviously been given by these junior teachers to such practical points as more detailed instruction in the nursing of the lying-in mother and the management of her infant. "How many students have watched a baby being breast-fed?" asked one, and then went on to argue that for part of his period of clerkship the student should be turned into a nurse. The maternity units in the London teaching hospitals were criticised as being too small, and it was hinted that more might be done by collecting the material into large hospitals and segregating



ANTIPHLOGISTINE

BRAND
DRESSING

in the treatment of

MASTITIS

On the first sign of inflammation and swelling of the mammary glands, Antiphlogistine Dressing, copiously applied, together with proper support of the breast, will usually lead to complete healing in a comparatively short period of time.

On account of its hyperæmic, osmotic and relaxant effects, Antiphlogistine Dressing brings about an early resolution of inflammation, and yields moist heat and plastic support—essential for the proper treatment of mastitis.

● ● ●

Antiphlogistine Dressing is recommended in standard medical works and text-books for the relief of this condition.

Sample and literature will be sent upon request

finding, but this record is important in view of the fact that Yugoslavia is an agricultural State with (as Sučić points out) 80 per cent. of its population engaged in farming and the like. This goes to show that the increase in pulmonary tumours is not confined to the populations of the air-polluted industrial centres of the world.

The fact of its increasing incidence makes cancer of the lung particularly interesting to pathologists at the present time, for one may reasonably assume that as the disease is on the increase so must the factors which are responsible for it be on the increase, and hence be the more readily identifiable. On this assumption a number of extraneous agents, associated with the modern increase of industrialism, have been cited as possible causes. These include road dusts, especially from tarred roads, exhaust gases from motor-cars, and factory smoke—all acting through the medium of air pollution. Yet the now well-established fact that these cancers are on the increase in agricultural lands as well as in industrial towns makes it difficult to associate them directly with industrialism, especially as the industries in the various countries concerned are so diverse. Sučić is driven to the conclusion that diverse factors must be concerned indirectly in the carcinogenesis, all of them acting as irritants to the bronchial mucous membrane or alveolar epithelium so as to predispose to cancer development. It is difficult to believe, however, that even a variety of factors could operate with such uniform effect in such diverse places, both urban and rural, as has been the case with the increase in cancer of the lung. One can believe that the atmosphere of large cities may have deteriorated in the last few decades, but not that the atmosphere of the countrysides can have altered correspondingly, and the simple fact that the cancer increase is so general and uniform seems largely to absolve industrial air pollution from blame. A factor which is of much more uniform distribution than industrialism and which merits careful consideration is tobacco-smoking. Already several authorities have suggested this—and especially cigarette-smoking—as a likely cause of lung cancer, and the notion is certainly gaining ground; yet there remains an evident reluctance on the part of many investigators to associate themselves with it. HOFFMAN[1] has discussed the question fairly fully, and amongst other notable facts he has pointed out that the consumption of light cigarettes has increased from 53,000 million to 108,000 million between the years 1918 and 1928. There is no doubt that men still remain greater tobacco-consumers than women, and the fact that practically all observers find cancer of the lung to be pre-eminently a disease of men, supports the suggestion of a direct relationship between it and smoking. Sučić noted that 25 of his 30 cases were in men, and many other observers have found the proportion in favour of men to be even greater than this. If air pollution of any kind is to be seriously considered, therefore, this particular form of it must not escape attention for, no matter whether he be in the fields of Yugoslavia, on the mountains of Innsbruck, or in the streets of Manchester, the cigarette-smoker who inhales habitually subjects himself to the most concentrated form of air pollution possible to endure.

Unfortunately, information about the personal habits of past cases is difficult to obtain, so that the data which might yield direct evidence on this point are wanting, and the answer must await the collection of further clinical observations. Several workers have of late tried to produce experimental proof that tobacco is carcinogenic—using such methods as subjecting animals to an atmosphere laden with cigarette smoke, or applying to their skins tar obtained from tobacco combustion. A feature of many of these experiments seems to have been the development of cancer in not more than one animal out of large numbers used in each instance. Such was the case with two independent workers in Germany[2] and the Argentine[3] and also with a group of workers in Birmingham[4] whose results have lately appeared. These negative results are, of course, from the nature of things biological, just such as are to be expected in early attempts at a new line of experimental cancer production, and it would be wrong to conclude from them that tobacco is unimportant as a factor in the causation of cancer. However difficult it may be to prove the case against cigarette-smoking, it has not yet been cleared from suspicion.

MEMORIAL TO DAME MARY SCHARLIEB.—A ward was dedicated to the memory of Dame Mary Scharlieb at the Royal Free Hospital on Tuesday last. The ceremony took place in the Mary Scharlieb obstetrics and gynæcology unit of the hospital. Miss Elizabeth Bolton, dean of the London School of Medicine for Women, who presided, referred to the work done by Dame Mary for medical women, for the hospital, and for the women of the Empire. Lady Barrett recalled that she was "a very great lady," and that her appointment to the Royal Free was due not to her being a woman but to her abilities as a surgeon. After Dr. Gladys Hill had expressed the admiration of the younger generation of medical women, the Bishop of London dedicated the ward and Lord Riddell, president of the hospital, unveiled the memorial tablet, whose inscription is as follows:—

> This ward commemorates the life and work of Dame Mary Scharlieb, D.B.E., M.S., M.D., D.C.L., J.P., 1845–1930, as gynæcologist to the Royal Free Hospital. She was the first woman to serve on the staff of any general hospital.

Dame Louise McIlroy offered the thanks of the hospital to those who have provided the memorial.

EXTENSION OF THE DREADNOUGHT HOSPITAL.—At the 111th annual court of the Seamen's Hospital Society, to be held at Greenwich at 3 P.M. on Wednesday, June 8th, the Duke of York, the president, will open the new surgical wing of the Dreadnought Hospital and the out-patient department. Until 1870 the hospital was housed in the old *Dreadnought* man-o'-war, which was moored off Greenwich, and had done duty from 1821. The present building and the new wing, named after the old ship, form one of the seven establishments of the society, which now cares for over 33,000 sick and injured seamen every year. It is still maintained by voluntary contributions.

the midwifery teaching there, but little was said of the very grave objections to the separation of obstetrical from gynæcological instruction which such a move would entail. There was general agreement that in institutions of sufficient size there should be a resident director whose services would always be available when those of an honorary visiting staff are not, but the further condition was laid down by one speaker that such whole-time resident director must also have had some years' experience of private practice, as in the case of the Master of the Rotunda, if he is to be a successful teacher for the future family practitioner.

The most satisfactory feature of the discussion was that the tutors and registrars who spoke showed no ambition to teach students the technique of the grand operations, but were anxious only to ensure that they mastered such every-day work as the conduct of normal labour in the home, and the nursing of mothers and infants. If we can assume that their outlook reflects that of their colleagues throughout the country, we can have confidence in the passing of the era of disruptive mechanical interference as a substitute for the leisurely process of nature.

◆

SILICOSIS.

THE old idea that inhaled dusts are injurious to the lungs in proportion to their physical hardness has now for some while been abandoned in favour of the view that they do damage by virtue of their content in silica, which is a tissue poison. Epidemiological evidence and animal experiment agree in coming to this conclusion, and it seems likely now that dusts which do not contain silica are practically innocuous unless the lymphatic apparatus of the lungs has been previously damaged by that substance. Under ordinary conditions of industrial and occupational exposure, the development of pulmonary fibrosis and of the corresponding symptoms is very slow. Relatively acute silicosis has been observed when the solubility of the silica is increased by the simultaneous inhalation of alkaline soaps in the manufacture of abrasive cleansers, but the examples of this recorded by Dr. G. MACDONALD[1] and Dr. E. M. CHAPMAN[2] were exposed for three or four years before anything abnormal was noticed; in the ordinary cases the latent period is 10 or 20 years. Once symptoms have appeared, nothing substantial can be done in the way of cure; it is therefore of the greatest importance that dangerous dusts should be known as soon as possible, the more so because the ingenuity of modern industry is liable at any time to introduce a new dust of which there is no previous experience. A good deal may be inferred from chemical analysis. But this is not infallible, for carborundum (silicon carbide) is in experience not found to be harmful. Prof. E. H. KETTLE has therefore done a very useful service in devising[3] a quick and simple animal test by which poisonous dusts can be identified. The dust in suspension is injected subcutaneously into a mouse which thereafter receives an emulsion of tubercle bacilli into the tail vein, and the local lesion is subsequently examined histologically. The substances he tested fell sharply into two groups: (*a*) active dusts which cause a lesion with local necrosis and a pronounced cellular reaction in which the tubercle bacilli accumulate and multiply; and (*b*) inert dusts which bring about little or no tissue reaction and which do not favour the growth of the bacilli. The inactive dusts include carbon, coal, aluminium oxide, oxide of iron, marble, and carborundum; the active dusts are in all cases siliceous and contain either amorphous or crystalline silica or silicates (quartz, shale dust, kaolin, and asbestos). Crystalline silica coated with iron oxide proved to be inert. This classification corresponds precisely with experience, except for kaolin, which in actual practice has not been shown to be harmful; Prof. KETTLE thinks, nevertheless, that in view of its composition (aluminium silicate) and the results of his experiments it should be regarded with something more than suspicion. Subcutaneous experimental lesions must, however, be supplemented by pulmonary ones if the actual mechanism of the onset and progress of silicosis as it occurs in humans is to be explored. Dissatisfied with the cumbersome expedient of dusting chambers he attempted some years ago to introduce dust into the lungs of rabbits and guinea-pigs by means of single or repeated intratracheal injections. These experiments had to be discontinued, but have recently been resumed in collaboration with Dr. R. HILTON. The results recorded elsewhere in this issue are promising, since the lesions produced with a minimal amount of trouble, expense and wastage, are typical of the well-recognised early silicotic nodules.

These are clearly important additions to the available means of attacking an insidious and distressing disease, the wide prevalence of which has been appreciated only when it has been looked for; we are probably still a good deal short in our estimate of the harm done by inhaled silica. Almost everyone must breathe in a certain amount, and it still remains to define the quantity which is injurious.

THE INCREASE IN CANCER OF THE LUNG

FROM centres in nearly all the populous districts in the northern hemisphere we now have reports of a progressive increase in the incidence of cancer of the lung. To the April issue of the *Wiener Archiv für innere Medizin* Dr. DINKO SUČIĆ contributes a paper on its occurrence in Zagreb in Yugoslavia. His material comprised in all 51 cases, 30 of which were investigated in the pathological institute of Zagreb University during the last ten years. In that institute lung cancers have increased from an average of less than 6 per cent. of all cancers in 1923–25 to more than 18 per cent. in 1929. Such an increase is no unusual finding, but this record is important in view of the fact that Yugoslavia is an agricultural State with (as Srčić points out) 80 per cent. of its population engaged in farming and the like. This goes to show that the increase in pulmonary tumours is not confined to the populations of the air-polluted industrial centres of the world.

THE INCREASE IN CANCER OF THE LUNG.

From centres in nearly all the populous districts in the northern hemisphere we now have reports of a progressive increase in the incidence of cancer of the lung. To the April issue of the *Wiener Archiv für innere Medizin* Dr. Dinko Sučić contributes a paper on its occurrence in Zagreb in Yugoslavia. His material comprised in all 51 cases, 30 of which were investigated in the pathological institute of Zagreb University during the last ten years. In that institute lung cancers have increased from an average of less than 6 per cent. of all cancers in 1923–25 to more than 18 per cent. in 1929. Such an increase is no unusual relatively small number of patients, but it may be said that Dr. Duffy's figures of over 20 per cent. of cases clinically free from disease after five to nine years are very encouraging. It should be noted that he employs a 4-gramme radium pack, and Dr. Berven a "gun" containing 3 g. of the element; it appears that, at the least, there is a strong case for further experimental work with large undivided quantities of radium in the treatment of cancer of these regions.

STITCH.

IN its original and complete meaning—a sharp acute pain in the intercostal region—the term "stitch" is rarely employed, although it may be frequently encountered in Shakespeare, and Dr. Percy Kidd, in Allbutt's "System of Medicine," refers to the "agonising stitch of pleurisy." In its limited more popular application, by stitch is generally understood the familiar pain in the side induced by sudden severe muscular exercise, especially if food has been taken only a short time previously. The genesis of stitch has always been of no little interest to athletes, since its occurrence usually demands cessation of the exercise. Some relation to the circulation has perhaps not unnaturally been regarded as the important factor; for example, it has been attributed to tension of the capsule of the spleen through congestion of the viscus, and references are forthcoming in classical and Biblical literature to the operation of splenectomy in runners as a preventive measure. To the objection that the right side of the body is sometimes or as often affected, supporters of the circulatory hypothesis incriminate the liver instead of, or equally with, the spleen, though the performance of hepatectomy was probably not contemplated even by our enterprising predecessors. That oarsmen, in whom the exertion is at least as violent as in runners, are immune from stitch was not considered an objection to the explanation, inasmuch as the muscular movements and the posture in boat-racing would encourage the expulsion of blood from the solid abdominal viscera and so avoid distension. The death blow to the circulatory hypothesis was however struck by Joseph Barcroft in his demonstration that the spleen during exercise is contracted, not distended. Furthermore, the same kind of pain is produced by riding a camel with a jerky action or a motor-cycle on a rough road, although in these circumstances any circulatory influences may be excluded. It becomes necessary therefore to construct a more satisfactory hypothesis based upon ligamentous or muscular phenomena. The subject is entertainingly considered in the *Guy's Hospital Gazette* of April 30th, with subsequent correspondence in a later number. The writer, E. T. C., regards as essential factors the erect posture and a jolting up and down movement. In the erect attitude, he points out, the heaviest viscera, the stomach, liver, and spleen, are partly supported by the musculature of the abdominal walls, and stitch appears in those situations where the walls are less able to provide adequate support, so that the vertical strain on the ligaments is much intensified. The idea that spasm of the diaphragm might be responsible was disproved by the experiments of four Guy's students who voluntarily induced stitch by running after a heavy meal, and in whom fluoroscopic examination failed to reveal any diminution or defect in diaphragmatic movement. During running, whilst maximum excursion of the respiratory musculature of both thorax and abdomen is essential, there is at each expiratory gasp complete relaxation of the muscles maintaining intra-abdominal pressure. If violent jolts coincide repeatedly with this relaxation, the result will be an intermittent tugging strain on the coronary and other ligaments, an "acute physiological visceroptosis" so to speak, an effect which the Guy's writer states will tend to disappear with the better coördinated respiratory movements when "second wind" is established—an opinion which will not, however, be corroborated by all long-distance runners. Stitch, it is clear, is more likely in the case of the untrained; it will be expected in cross-country running where the surfaces to be traversed are rough and irregular, and also in certain runners whose imperfections of style and action lead to jerkiness and vibration. In all probability there is also a constitutional predisposing factor, since, as is well known to clinicians, visceroptosis is productive of symptoms only in those subjects with the appropriate receptive mechanism.

THE LIFE-HISTORY OF TREPONEMA PALLIDUM.

IN a recent examination for a post-graduate degree, a question was asked on the life-history of spirochætes. The marking of the answers must have proved a difficulty; it would be a brave and a learned examiner indeed who could vote any answer either right or wrong. The life-history of *Treponema pallidum* is, in fact, quite uncertain. Some authors, such as Noguchi, held that it simply splits in two; others, such as McDonagh, believe that it has a cycle as complex as that of the malarial parasites. It may be surprising to the reader who has not maintained contact with recent work on syphilis to discover, in a review by Dr. Norman Ingraham,[1] that there are serious reasons for doubting such statements as that the treponema has been cultivated; and that many distinguished workers are not sure that the familiar organism of the dark-ground field is the form, even if it is the species, which transmits the disease. When a piece of syphilitic tissue is placed in culture medium, it is true that treponemata are later found in it. But they may only have migrated from the tissue. And what is happening in the incubation period, when the organisms are not found, or in the tertiary or parasyphilitic stages, when they are only rarely discovered? Even in congenital syphilis, which every student imagines to be characterised by a liver swarming with parasites, actually only one-third of the cases show them. Moreover, arsenical preparations certainly kill the familiar treponema; but they do not always cure syphilis. Is this because the parasite becomes arsenic-resistant? Or because it lurks, entrenched and secure from attack, in some vaguely imagined privacy? Or because it passes through a phase which is arsenic-proof? A further difficulty concerning the treponema is that even those who claim to cultivate it admit that old cultures and subcultures are non-infective. Is this because in them the intermediate, infective stage is lacking?

When, however, we look for suggestions as to how the organism multiplies, we find most contradictory evidence. McDonagh, who first pointed out that dividing forms were absent in scrapings of chancres, stated in 1912 that he had seen the organism developing from a sporozoite through sexual forms (including a "spirochæte") to a minute infective spore. He called the parasite the "leucocytozoon syphilidis." As Ingraham points out, the only published

ANNOTATIONS

CHLOROFORM AND THE HEART.

CHLOROFORM is a cardiac poison, and in experiments on animals produces certain disturbances of the heart rhythm which appear in a definite order. First there are isolated premature contractions of the ventricle, then multiple beats of the same kind, and still later paroxysmal ventricular tachycardia. Finally, the injury to the muscle culminates in ventricular fibrillation—a fatal condition, since when the muscle contracts in this particular way it can do no useful work. About 20 years ago A. Goodman Levy did valuable work in showing that in cats under light chloroform anæsthesia slight stimuli of various kinds, such as a small injection of adrenaline, or the stimulation of a sensory nerve, or even lifting the animal, were sufficient to cause ventricular fibrillation. In man sudden death during the induction of anæsthesia with chloroform sometimes occurs, and there is strong evidence that this is due to ventricular fibrillation. Although an electrocardiogram showing the heart mechanism in a fatal case of this kind has never been obtained, Dr. I. G. W. Hill, in our last issue, reported some interesting observations on the electrocardiogram taken in the induction stage. Among 16 cases some abnormality was noted in all but three. Bradycardia, and the disappearance of the P waves (which is probably to be interpreted as nodal rhythm), was noted in three instances, but ventricular premature beats, either single or multiple, were the commonest irregularity. Deeper anæsthesia led, nearly always, to their disappearance. That there are risks attending the use of chloroform has also recently been pointed out by Dr. R. W. Hornabrook [1] who heroically submitted himself to anæsthesia under several different conditions. In one experiment the anæsthetic was given when the subject was in a fatigued condition. The pulse became slow and the tracing showed auriculo-ventricular nodal rhythm; at the same time his condition gave rise to some anxiety. He believes that certain precautions will render undesirable effects on the cardiac rhythm much less likely; thus it is suggested that these may be avoided if chloroform is not given to patients who are fatigued, if it is preceded by an injection of morphia and atropine, and if it is administered in the sitting posture or with the head and shoulders raised, when struggling is much less probable. With or without precautions, however, it would appear from these investigations that the patient under light chloroform anæsthesia is often in a precarious condition.

TREATMENT OF CARCINOMA OF TONSIL.

IN a recent paper, Dr. James Duffy [2] reviews the experience of the New York Memorial Hospital in the treatment of 122 cases of carcinoma of the tonsil. He believes that true sarcoma is very rare in this locality and that the majority of cases so described, with early glandular metastases, should, in reality, be classified as lympho-epithelioma. His cases are divided into Grades I., II., and III., and transitional: Grade I. is a radio-resistant, highly squamous type; Grade II., intermediate; and Grade III. has lost its squamous characteristics, and is radio-sensitive; this latter grade, as he admits, might be combined in classification with the transitional type. He considers the results of surgical extirpation so bad that tonsillar carcinoma in any stage must be classed as surgically inoperable, and cannot therefore be divided into operable and inoperable cases; he classifies his cases therefore into the three groups of those with no palpable metastases, those with surgically operable, and those with inoperable cervical metastases. The treatment given is usually a combination of external and interstitial radiation. Both sides of the neck are subjected to a high-voltage X ray beam which includes the primary lesion and the lymph drainage areas, and immediately afterwards a radium pack is directed over the primary growth and the adjacent cervical region. These radiations are given in full erythema dosage and deliver 150 to 180 per cent. of a skin erythema dose to the tonsillar growth. Radon in gold tubes is then implanted into the tumour, in quantity depending on its size, on its histological gradation, and on the clinical response to the external radiation. If there are no cervical metastases on admission, the patient is carefully observed at frequent intervals; if operable metastases develop, or are present on admission, a full and complete dissection is performed, including both anterior and posterior triangles with resection of the sternomastoid muscle and the jugular vein. To be classified as operable, the metastases must not have infiltrated the capsule; they must, except in rare instances, be limited to the same side of the neck as the primary lesion, and the histological grade must be in the more fully differentiated class. If the primary growth is of a very radio-sensitive type, extirpation is not undertaken, but radon in full dosage is implanted in gold tubes after surgical exposure of the node. In inoperable cases the radon is buried through the skin without incision. For discussion of the results of treatment, the cases are divided into those treated from 1921 to 1924, and those from 1925 to 1928 inclusive. As the data were collected in 1929, only patients in the first class can be included in the five-year group; of these there were 49 in all, of which 10, or 20·4 per cent., remain clinically free of disease from five to nine years after the beginning of treatment. Although it is too soon to use the second group for comparison, the figures for the development of cervical metastases show a considerable improvement; the external radiation dosage was increased about 1925, and later a 4-gramme radium pack was added to the equipment. But a decrease in local recurrences from 30 to 24 per cent. is ascribed to the use of gold radon tubes instead of bare glass seeds. Of the radiation transmitted by the glass seed, 96·5 per cent. are beta rays and 3·5 per cent. gamma rays; whereas, with a 0·3 mm. gold filter the proportions are 8·8 and 91·2 per cent. respectively. As might be expected, with the elimination of nearly all the soft necrosing beta rays, the results are far better, and a platinum or gold filter is now almost universally employed in interstitial radiation. The method of treatment of cervical metastases is somewhat similar to that employed by Dr. Elis Berven,[3] in Stockholm, which was noted in our columns at the end of last year; but Dr. Berven prefers teleradium treatment, or the emanation from a large quantity of radium at a distance of 4 to 6 cm., to X rays as causing less reaction and dysphagia. Cases come for treatment at such various stages of the disease that it is of little value to compare the results of treatment of a tropics. Taking a census is not likely to be an easy job when the population to be enumerated gets it into its head that "England has suddenly become unbearably hot. Queen Victoria desires virgins from each village in the territory to fan her day and night, and the census provides the means of selecting individuals for this purpose." Yet it is less than 200 years ago that the taking of a census in this country was opposed in the House of Commons on the grounds that Jehovah did not approve of the numbering of the people. A beginning must be made sometime even if it be on only a very small scale. In fact Major Edge goes so far as to propose that the best line of approach may lie in small-scale intensive inquiries, gradually widening in extent as means become available and as the inhabitants become inured to the cross-examinations by officials and the processes of registration.

RESPIRATORY FAILURE IN ACUTE ANTERIOR POLIOMYELITIS.

A DESCRIPTION of the Drinker-Shaw respirator, an apparatus designed for the prolonged administration of artificial respiration, and extensively used in America for the treatment of carbon monoxide poisoning, was given by Mr. Philip Drinker in our columns last year (1931, i., 1186). Dr. J. L. Wilson[1] has now reviewed 90 cases at the Children's Hospital, Boston, in which it was used in the treatment of respiratory failure due to anterior poliomyelitis. In this disease respiratory failure may come on in three different ways, which it is important (though often difficult) to distinguish clinically. There may be direct paralysis of the intercostal muscles and diaphragm due to "spinal" distribution of the disease; while a "bulbar" type of case may show either pharyngeal paralysis, causing interference with respiration from accumulations of secretion around the glottis, or paralysis of the respiratory nerve-centres in the medulla. The treatment and prognosis will be somewhat different in the three types. The object of artificial respiration will in each case, however, be to rest as far as possible paralysed muscles (in accordance with the orthopædic principles applied in the early treatment of the disease), to avoid exhaustion, and to abolish cyanosis—since, apart from the distress that cyanosis indicates, anoxæmia may actually contribute to the destruction of nerve tissue. Where there is pharyngeal paralysis, suction must be used for the removal of secretion from the glottis, and Wilson advocates the parenteral and rectal administration of saline and carbohydrate until the paralysed muscles show some degree of recovery. In this way the stomach is kept empty, and the danger of vomiting and inhalation of fluid—a frequent sequela of tube-feeding in these cases—is avoided. A tracheotomy may be necessary. Among 23 cases of the "spinal" type treated in the respirator, there were two deaths from pneumonia and one (in an adult) secondary to infected bed-sores. While no claim is made that the condition in all the remaining 20 would, in the absence of artificial respiration, have proved fatal, the low mortality is very striking. Also, since the date of two of the fatalities, technical improvements have been made in the apparatus which permit of frequent changes of position—an important factor in preventing both bed-sores and pneumonia—and all necessary nursing procedures to be carried out without removal of the patient from the apparatus. As would be expected, the percentage mortality in the group of bulbar cases treated was considerably higher, but here too the results were remarkable in view of the very high normal mortality. From the experience gained in the treatment of these cases, Wilson emphasises three important principles to be followed when the respirator is employed. It must be used as *early* as possible after the onset of the paralysis, and before the onset of cyanosis and dyspnœa. Delay often results in a sudden increase in symptoms and severe collapse, when transport to the apparatus may not be sufficiently rapid to save life. Treatment must be prolonged. Exhaustion of the affected muscles is apt to take place suddenly after premature removal from the respirator, although for short periods the respiratory function may appear to have recovered. It is also necessary to keep in mind the possible danger of tetany, but this is very unlikely to develop if care is taken to avoid over-ventilation of the lungs. It is clear from Wilson's results that the Drinker-Shaw respirator represents a real advance in the treatment of what is, happily, a comparatively rare type of case. Death from paralysis of the respiratory muscles is perhaps more distressing than any other, since it consists of slow suffocation whilst full consciousness is retained almost to the end. Undoubtedly the most striking feature of treatment with the respirator is the intense relief afforded to the patient—relief so marked that he will often fall into deep and prolonged sleep after the first few breaths within the apparatus.

PRECAUTIONS AGAINST SHOCK DURING ELECTROTHERAPY.

THE risk of serious electric shock is acknowledged to be greater from alternating currents, which are now increasingly used for the main supplies throughout the country, than from direct currents. On industrial premises 30 fatalities due to shock from alternating currents at between 200 and 250 volts have occurred during the past five years, as compared with one due to direct currents of similar voltages. In a memorandum (Memo. 161 Med.) to county and county borough councils the Ministry of Health outline precautions against shock from electromedical apparatus, careful attention to which should go far to minimise the risk of accident. It is obvious that old and improperly insulated apparatus is in itself a grave source of danger. A recent fatality was due to loose fastenings in the metal holders of a radiant heat bath, the patient under treatment being electrocuted when he grasped the bedstead, which was in contact with a hot-water pipe. It is essential when patients are receiving electrical treatment in bed that the iron bedstead should not be in contact with any earthed metal—e.g., heating or water pipes, radiators, or even an "earthed" wireless receiver. Where apparatus not insulated from mains is in use, it is undesirable that patients undergoing treatment simultaneously in the same room or ward should be within reach of each other. The source of supply for heat treatment by electrothermal compresses should always be at low voltage. Patients wearing wireless headphones while undergoing electrical treatment, or handling electrical apparatus, should be protected by the insulation of the output circuit to which the headphones are connected. Internal mesh guards should be fitted to the lamps and holders in radiant heat baths, and to projectors for light treatment. In general the use of sets for generating electricity (as galvanic, faradic, and sinusoidal currents) which are not isolated electrically from the source references to work on this theory confirm it; much as (according to Chesterton) all the evidence on the question of ghosts is positive. McDonagh himself has since left the narrower field of syphilitic ætiology; but it is certainly strange that his work, which has been confirmed, is not more often mentioned and tested. Again, there is great difference of opinion as to whether the organism is filtrable or not. The question is possibly insoluble. When positive inoculations or cultures are stated to have been obtained from treponema-free filtrates, it is impossible to deny the argument that a few were overlooked. A second method of division has been suggested by Meirowsky, who believes the treponema to be a higher fungus. It was stated to be a protozoon by Noguchi, for a number of reasons, most of which are now held to be false. Meirowsky states he has seen the parasite bud. Levaditi and others hold that it goes through stages from an ultramicroscopic particle to the full fledged spiral. Quite apart from this observation, they contrast the almost invariable virulence of lymph glands, in early syphilis, with the absence of parasites. This fact, they explain, is due to its existence in a filter-passing stage.

---

[1] New Eng. Jour. Med., April 28th, p. 887.

The conflict of evidence is highly confusing. The difficulties of the case are, of course, largely due to the optical peculiarities of the ultramicroscope. Even in the hands of the expert it is a treacherous instrument; in the hands of the inexpert it is responsible for a high percentage of laboratory "howlers." There are few things as certain as that the *Treponema pallidum* causes syphilis. But whether it does so in the form familiar to us, or what its life-history may be, are very far from proven; fit questions as yet for the post-graduate examiner.

DIPHTHERIA IMMUNISATION IN INFANTS.

THERE is reason to think that if active immunisation is to make any substantial reduction in the incidence of diphtheria in a community the effort must be concentrated on children of pre-school age.[1] If so, it is important to determine the youngest age at which it is profitable to begin. It is known that most infants, of town-bred mothers at least, possess at birth sufficient maternally transmitted passive immunity to render the Schick test negative. This transmitted immunity persists in the majority at Schick-negative level for about three months and then wanes somewhat rapidly until at six months of age a high percentage of infants are Schick-positive and therefore at risk following exposure to infection. In some infants this passive immunity is lost more slowly and the Schick test may change, for this reason, from negative to positive within the first three years of life. The acquirement of active immunity as the result of subclinical doses of infection may again reverse the Schick test which then becomes permanently negative. In a recent paper J. Blum[2] draws attention to the effect of transmitted maternal immunity upon the success of active immunisation. In a home for infants Schick tests were performed at frequent intervals varying from six months to three years after immunisation. It was found that the percentage of positive reactions to the first test after immunisation from birth to nine months of age was less than the percentage of positive reactions to the later test. The greatest proportion of positive reactions following immunisation (32·4 per cent.) occurred amongst infants from birth to three months, and the smallest proportion (5·4 per cent.) amongst the oldest children of from two to four years of age. The proportion of positive reactors in the three to six months and six to nine months groups was the same (25·7 per cent.), whereas in the nine to twelve months and one to two year groups the percentages were 15·4 and 8·3 respectively. These figures demonstrate clearly a fact which is well known to immunologists—namely, that the existence of passive immunity may damp down and render less effective the stimulus of the prophylactic to the production of antitoxin by the tissues. The response is poor. While it is customary in many immunisation clinics, and should be in all, to perform whenever possible a confirmatory Schick test at an interval after immunisation in order to ascertain the fact of immunity, the preliminary Schick test, on grounds of expediency and economy of time, is often omitted in the case of children under 6 or even 8 years of age. After that age the preliminary test is desirable not only because the proportion of natural immunes may be considerable, thus rendering injections unnecessary, but also because the children may have become protein-sensitive, and a modified dosage may be required. Unless the Canadian "reaction test,"[3] which consists in the intradermal injection of a small amount of diluted toxoid, is employed, sensitiveness to the proteins contained in the prophylactic is only to be ascertained by the appearance of a pseudo-element in the Schick test. As Blum points out, if it is desired to immunise young infants, the best time to begin in order to get a satisfactory response is when the passive immunity inherited from the mother is lost. This, again, is only to be determined by a preliminary Schick test, which he urges should never be omitted before immunisation in the case of infants under 9 months of age. Omission of the test, Blum says, is hazardous and may lead, as his data show, to a false sense of security. It would seem that the practice adopted by many clinics in this country of beginning immunisation at 12 months of age is reasonable and permits, if practical difficulties exist, of the omission of the preliminary Schick test. Before that age the test should always be done.

THE COLLECTION OF STATISTICS IN THE TROPICS.

THE elaborate systems in vogue for the collection and publication of vital statistics in modern civilised states are certainly not without their critics—whose numbers are likely to increase in these times of national economy. The majority of persons interested in problems of public health are, however, agreed that accurate vital records are the most satisfactory yardstick by which the success or failure of public health measures and of the applications of preventive medicine can be gauged. What is true of western civilisations is no less true of the tropics. But in the latter at the present time the yardstick is nearly entirely absent. Even when statistical records are included in official reports they are often valueless, as their authors cheerfully admit, owing to their unreliability. Major Edge's object in a little book reviewed on another page is to examine the difficulties in the collection of accurate vital statistics in tropical territories, and to outline schemes by which he considers the essential data could eventually be secured. The process is likely to be very slow and Major Edge makes no attempt to minimise the difficulties facing the worker in the tropics. Taking a census is not likely to be an easy job when the population to be enumerated gets it into its head that "England has suddenly become unbearably hot, Queen Victoria desires virgins from each village in the territory to fan her day and night, and the census provides the means of selecting individuals for this purpose." Yet it is less than 200 years ago that the taking of a census in this country was opposed in the House of Commons on the grounds that Jehovah did not approve of the numbering of the people. A beginning must be made sometime even if it be on only a very small scale. In fact Major Edge goes so far as to propose that the best line of approach may lie in small-scale intensive inquiries, gradually widening in extent as means become available and as the inhabitants become inured to the cross-examinations by officials and the processes of registration.

Where apparatus not insulated from mains is in use, it is undesirable that patients undergoing treatment simultaneously in the same room or ward should be within reach of each other. The source of supply for heat treatment by electrothermal compresses should always be at low voltage. Patients wearing wireless headphones while undergoing electrical treatment, or handling electrical apparatus, should be protected by the insulation of the output circuit to which the headphones are connected. Internal mesh guards should be fitted to the lamps and holders in radiant heat baths, and to projectors for light treatment. In general the use of sets for generating electricity (as galvanic, faradic, and sinusoidal currents) which are not isolated electrically from the source of main supply, is deprecated. In the safer method of construction known as "earth free," electric shock at mains pressure would be possible only if a breakdown of insulation between the two systems occurred, and in good-class apparatus there seems to be no great risk of this occurring. For medical diathermy treatment the apparatus favoured is that which makes provision for the patient's circuit to be isolated electrically from the intermediate (or spark gap) circuit; the spark gap to be mounted inside the cabinet or enclosure containing the apparatus; the door of the cabinet or enclosure to be interlocked with the source of main supply so that the latter is disconnected when the door is opened. Regular and systematic inspection by competent experts should be made of all electromedical apparatus to ensure the maintenance of efficient insulation.

THE BRITISH LEGION VILLAGE.

In April, 1925, when the British Legion took over the activities at Preston Hall, there were some 27 settlers —tuberculous ex-Service men—left by its predecessors, the Industrial Settlements Incorporated. At the end of September, 1931, there were 230 patients in the sanatorium, 555 in the Settlement, and a staff of 44. The institution, therefore, well deserves the title of "village." When a patient has been discharged from the sanatorium he lives in the hostel, if single, and in a house in the village with his wife and family if married. He is given the medical attention, sheltered employment, hygienic conditions, and social environment that he needs. He is on the panel of the medical director, and therefore eligible for all benefits under the National Health Insurance Acts, and his children attend the child welfare centre in the village. His dependents have the benefit of routine medical examination and are, on the whole, extraordinarily healthy. Not a single child has developed pulmonary tuberculosis, and among the 58 births which have taken place there has not been a single case of tuberculous meningitis. Dr. J. B. McDougall, the medical director, ascribes these happy results to the social environment; the freedom from worry and the relatively high standard of living. There is urgent need for more room for settlers, and the council feels that the local authorities, which have hitherto contributed nothing, should take their share in further expansion. The industries include the manufacture of portable buildings and travelling goods, a wood-graining department, a printing department, a live-stock department, and a village store. In the year ending Sept. 30th, 1931, the industries spent £30,368; paid £18,084 in salaries, wages, and commissions; and received from sales £54,571. The prosperity of the industries in the face of world-wide depression has been remarkable, and most of the departments are self-supporting. The appliance department has carried out work for a number of county, urban and rural district councils, and the high standard of the printing department, which sells £9000 worth of print per annum, is manifest in the format of the annual report. During the year, 351 patients were admitted to and 297 were discharged from the sanatorium section. Besides the necessary clinical work, in which artificial pneumothorax plays a large part, some research on the cellular content of tuberculous blood has been undertaken. The work includes a valuable after-care department, which sees that ex-patients get a fair chance in their struggle with life.

NARROW SPECIALISATION.

THE alternative educational system, characteristic of our public schools, which involves choice at an early age between the humanities and science, marks a transitional period. The distinction between the classical and modern side of a school is already less rigid than it was, and there is much overlapping. Most educational authorities are in fact agreed that anyhow up to the age of 16 specialisation should be discouraged. Unfortunately, however, as Sir Walter Fletcher pointed out in the course of an address to the Royal Institution last Friday, narrow specialisation after that age, and indeed throughout the undergraduate's career, has been pushed to excess. It is possible, and even usual, for students of physics and chemistry to proceed through school life and to a university degree without ever being made aware of the relevance of their work to matter endowed with life. The system under which university scholarships are allocated naturally influences the teaching in the higher forms of schools, and encourages concentration on physics and chemistry to the exclusion of biology. In a leading article in *Nature* last week W. H. G. deplores the spoon-feeding of ordinary students to enable them to gain honours degrees, since this policy favours "the present highly specialised school science teaching with its shocking neglect of biological science." Sir Walter Fletcher has peculiar opportunities for watching the subsequent development of the raw material from which students of science are made, and his comments merit close attention. It is wholly wrong, he contends, that the acquisition of manipulative and analytical skill should be associated chiefly with inanimate matter, when it is so urgently needed for the service of biochemistry and biophysics. It is to this absence of a broad basis of training that Sir Walter attributes the fact that organic chemists have been less active in promoting the growth of biochemistry than have physiologists. His plea for the encouragement of the more general study of living matter was the more effective since it followed a masterly survey of recent history in medical research. He showed how the varied fields now being explored call at every point for the intensive application of physics and chemistry, and illustrated by apt examples the absurdity of allowing artificial boundaries to separate the different sciences on which progress in medicine must depend.

WE regret to announce the death on May 30th of Dr. Remington Hobbs, medical superintendent of St. Mary Abbot's Hospital, and consulting gynæcologist to the borough of Kensington.

THE executive committee of the British Social Hygiene Council announce that, after further consultation with representatives of the British Medical Association, they have decided to abandon their proposal to approve the opening by their secretary-general of an economically self-supporting personal problems bureau, under the auspices of the Council, as to do this might be held to render it impossible for the British Medical Association to continue to be represented on the Council. At the request of the committee Mrs. Neville Rolfe has agreed in the circumstances not to proceed with this project.

SOME THOUGHTS ON MEDICAL EDUCATION.*

BY SOMERVILLE HASTINGS, M.S.LOND., F.R.C.S. ENG.

THE medical profession in England is recruited to-day from a small proportion—approximately one-sixth—of the population, and all the ability and skill that exists in the other five-sixths is, as far as the science and practice of medicine is concerned, entirely wasted. I am aware that there exist many scholarships providing free of all cost a complete course of study for a medical degree, but unfortunately the student has to be fed and clothed and housed whilst he receives instruction. I am also aware that there are some 200 university scholarships given yearly by the Board of Education by which not only educational facilities but also an adequate sum for maintenance is provided. These scholarships are however tenable for at the most four years and a course of study for a medical degree takes at least five. As far as I have been able to discover there is not in England a single maintenance scholarship which will enable a boy or girl, whose parents are unable to maintain him/her without earning, to become qualified as a doctor. It may be objected that it is always possible for such an individual to take up some other trade or profession and, having saved money, to enter as a medical student. In exceptional cases this may of course be possible, but the best time for learning is immediately after leaving school, so that those who have spent several years in some other calling will find it difficult to start afresh their career as students.

MAINTENANCE SCHOLARSHIPS.

What we require are maintenance scholarships from the secondary schools to enable boys and girls who have the capacity to qualify as doctors and dentists to do so without any cost to their parents. If the nation so desired it, a provision could be made that those accepting such scholarships should agree to undertake service wherever this was required for the first three years after qualification, as is done in Russia. Under conditions of financial stringency, such as exist at present, it is not likely that the medical schools would raise any objection to accepting such students. If they did it would be a simple matter to found medical schools attached to the municipal hospitals, many of which are not only larger than the voluntary hospitals but contain clinical material of greater value for teaching purposes for those who will be entering general practice. The presence of students in a hospital is definitely advantageous to the patients. Students tend to keep the medical staff up to the scratch and attract to a hospital the best physicians and surgeons, because many of these are fond of teaching for its own sake and also because students when qualified are likely to call into consultation those whose opinions they have learned to value and respect. The foundation of medical schools at municipal hospitals would therefore be advantageous to these hospitals.

In Russia, where the whole cost of medical training is borne by the State, students are for the most part recruited from the factories and collective farms. Young men and women of promise are nominated by the local soviets and, if found suitable, are given a five years' course of training. This method is said to be yielding very good results. It must have this advantage, that the student will commence his studies with some knowledge and experience of the world as it really is. His outlook will not be confined to that of the nursery and public school as was the case with many of us. And because of this he will be able to appreciate much more fully the importance of environment in the ætiology and prevention of disease. On the other hand, he will probably be able to cram his mind less easily with that useless knowledge that most of us have been able to forget so successfully directly our examinations were past.

TRAINING FOR THE FUTURE.

The training of the medical student must be carried out on the assumption that he will probably live for some 30 or 40 years. We must therefore prepare his mind for changes that are inevitable in the organisation of the profession as well as for advances in scientific knowledge. The saying that "the centre of knowledge is for ever shifting" is surely true of the science and practice of medicine. We cannot of course tell in what directions progress will be made, but during recent years the physical sciences have been called in to an increasing extent to assist medicine, and marked advances have taken place in biochemistry. The curriculum is already much overloaded, but I think the burden could be reduced if more principles and less detail were taught and if a good deal of pharmacy and those parts of anatomy and physiology that can have no bearing on practical medicine were cut out. I am speaking now of the training of the general practitioner. Above all else the training in the preliminary sciences should be directed to the development of the type of mind that will collect all the facts and look at all sides of a question instead of jumping to a conclusion.

The human body differs so markedly from a cabbage that I fail to see what good purpose is served by teaching a medical student anything more than the most elementary principles of botany as a part of biology. There is far too much separation between the different subjects of the curriculum. The student takes his first and second examinations, and at once forgets most of what he has learned because it is not evident to him that these preliminary subjects have anything to do with what will be his life's work. The bearing of these on the study of medicine should be made clearer, so that the student may see his course of study as a continuous process designed to make him an efficient doctor.

A large proportion of the cost of medical education is borne by the State. It has reached as much as 60 per cent. in the case of one medical school and averages about one-third of the total amount expended. The practitioner has, therefore, definite obligations to the State that has helped to pay for his education, and can never justly regard himself merely as a private trader. His activities are already controlled and restricted in different ways. He is compelled by law to notify certain diseases, to give certificates of the cause of death, to order certain drugs only under prescribed conditions, and so on. The student must be taught to realise that his activities are of such of main supply, is deprecated. In the safer method of construction known as "earth free," electric shock at mains pressure would be possible only if a breakdown of insulation between the two systems occurred, and in good-class apparatus there seems to be no great risk of this occurring. For medical diathermy treatment the apparatus favoured is that which makes provision for the patient's circuit to be isolated electrically from the intermediate (or spark gap) circuit; the spark gap to be mounted inside the cabinet or enclosure containing the apparatus; the door of the cabinet or enclosure to be interlocked with the source of main supply so that the latter is disconnected when the door is opened. Regular and systematic inspection by competent experts should be made of all electromedical apparatus to ensure the maintenance of efficient insulation.

---

* Presidential address to the Socialist Medical Association on May 29th, 1932.

THE BRITISH LEGION VILLAGE.

IN April, 1925, when the British Legion took over the activities at Preston Hall, there were some 27 settlers —tuberculous ex-Service men—left by its predecessors, the Industrial Settlements Incorporated. At the end of September, 1931, there were 230 patients in the sanatorium, 555 in the Settlement, and a staff of 44. The institution, therefore, well deserves the title of "village." When a patient has been discharged from the sanatorium he lives in the hostel, if single, and in a house in the village with his wife and family if married. He is given the medical attention, sheltered employment, hygienic conditions, and social environment that he needs. He is on the panel of the medical director, and therefore eligible for all benefits under the National Health Insurance Acts, and his children attend the child welfare centre in the village. His dependents have the benefit of routine medical examination and are, on the whole, extraordinarily healthy. Not a single child has developed pulmonary tuberculosis, and among the 58 births which have taken place there has not been a single case of tuberculous meningitis. Dr. J. B. McDougall, the medical director, ascribes these happy results to the social environment; the freedom from worry and the relatively high standard of living. There is urgent need for more room for settlers, and the council feels that the local authorities, which have hitherto contributed nothing, should take their share in further expansion. The industries include the manufacture of portable buildings and travelling goods, a wood-graining department, a printing department, a live-stock department, and a village store. In the year ending Sept. 30th, 1931, the industries spent £30,368; paid £18,084 in salaries, wages, and commissions; and received from sales £54,571. The prosperity of the industries in the face of world-wide depression has been remarkable, and most of the departments are self-supporting. The appliance department has carried out work for a number of county, urban and rural district councils, and the high standard of the printing department, which sells £9000 worth of print per annum, is manifest in the format of the annual report. During the year, 351 patients were admitted to and 297 were discharged from the sanatorium section. Besides the necessary clinical work, in which artificial pneumothorax plays a large part, some research on the cellular content of tuberculous blood has been undertaken. The work includes a valuable after-care department, which sees that ex-patients get a fair chance in their struggle with life.

NARROW SPECIALISATION.

THE alternative educational system, characteristic of our public schools, which involves choice at an early age between the humanities and science, marks a transitional period. The distinction between the classical and modern side of a school is already less rigid than it was, and there is much overlapping. Most educational authorities are in fact agreed that anyhow up to the age of 16 specialisation should be discouraged. Unfortunately, however, as Sir Walter Fletcher pointed out in the course of an address to the Royal Institution last Friday, narrow specialisation after that age, and indeed throughout the undergraduate's career, has been pushed to excess. It is possible, and even usual, for students of physics and chemistry to proceed through school life and to a university degree without ever being made aware of the relevance of their work to matter endowed with life. The system under which university scholarships are allocated naturally influences the teaching in the higher forms of schools, and encourages concentration on physics and chemistry to the exclusion of biology. In a leading article in *Nature* last week W. H. G. deplores the spoon-feeding of ordinary students to enable them to gain honours degrees, since this policy favours "the present highly specialised school science teaching with its shocking neglect of biological science." Sir Walter Fletcher has peculiar opportunities for watching the subsequent development of the raw material from which students of science are made, and his comments merit close attention. It is wholly wrong, he contends, that the acquisition of manipulative and analytical skill should be associated chiefly with inanimate matter, when it is so urgently needed for the service of biochemistry and biophysics. It is to this absence of a broad basis of training that Sir Walter attributes the fact that organic chemists have been less active in promoting the growth of biochemistry than have physiologists. His plea for the encouragement of the more general study of living matter was the more effective since it followed a masterly survey of recent history in medical research. He showed how the varied fields now being explored call at every point for the intensive application of physics and chemistry, and illustrated by apt examples the absurdity of allowing artificial boundaries to separate the different sciences on which progress in medicine must depend.

WE regret to announce the death on May 30th of Dr. Remington Hobbs, medical superintendent of St. Mary Abbot's Hospital, and consulting gynæcologist to the borough of Kensington.

THE executive committee of the British Social Hygiene Council announce that, after further consultation with representatives of the British Medical Association, they have decided to abandon their proposal to approve the opening by their secretary-general of an economically self-supporting personal problems bureau, under the auspices of the Council, as to do this might be held to render it impossible for the British Medical Association to continue to be represented on the Council. At the request of the committee Mrs. Neville Rolfe has agreed in the circumstances not to proceed with this project.

GENERAL MEDICAL COUNCIL.

SUMMER SESSION, MAY 24TH–28TH, 1932.

Penal Cases reported by the Dental Board.

THE Council ordered the erasure from the Dental Register of the names of the following practitioners, "Dentists, 1921," who had been reported by the Dental Board for obtaining money from friendly societies under false pretences: Frank Cecil Earle, 64, Glencoe-street, Anlaby-road, Hull. Archibald MacNab Robertson, 16, Rosefield-avenue, Portobello, Midlothian. William Patrick Donnelly, 33, Templemore-avenue, Belfast. The first-named had also been found guilty of covering an unqualified practitioner.

Penal Cases adjourned from Previous Sessions.

The Case of James Gordon Bell, M.C., registered as of 47, Barrow-road, Bristol, L.R.C.P. Edin. 1914, L.R.C.S. Edin. 1914, L.R.F.P.S. Glasg. 1914, M.B., Ch.B. 1914, U. Edin., who had been summoned to appear before the Council on Nov. 27th, 1930, on the following charge:—

> "That you were convicted of the following misdemeanours,—viz.: (1) On Feb. 21st, 1928, at the Sheriff Court, Stirling, of driving a motor-car recklessly while in a state of intoxication, and were fined £15, licence suspended until date of expiry, and prohibited from obtaining another for two years thereafter; (2) On May 5th, 1930, at the Sheriff Court, Dunfermline, of driving a motor-car negligently, and driving said motor-car against a tramway car, and were fined £3, current licence suspended, and disqualified from obtaining another for five years from expiry of current licence; (3) On May 17th, 1930, at Edinburgh Police Court, of being drunk and incapable, and were fined 15*s.* or ten days' imprisonment."

The Council had postponed judgment in June 1931, subject to the usual conditions of good behaviour and the production of favourable written testimony from a number of professional brethren.

Dr. Bell appeared but was not represented. Mr. Harper, solicitor to the Council, read testimonials written by certain medical men on the respondent's behalf, and a letter written to himself by the respondent.

Dr. Bell, examined as a witness, said that he was trying to build up a practice, but that his health was poor. The Council decided not to erase his name from the Register.

The Case of Alan Gray, registered as of 65, Moston-lane, Blackley, Manchester, M.B., B.S. 1925, U. Durh., who had been summoned to appear before the Council on the following charge:—

> "That you were convicted of the following misdemeanours—viz.: (1) On Sept. 13th, 1927, at the Blyth Police Court, of being drunk in charge of a motor-cycle, and were fined £1 and £1 11*s.* costs, and of driving the motor-cycle to the danger of the public, and were fined £1. (2) On June 15th, 1931, at the Middleton Borough Police Court, of attempting to drive a motor-car whilst under the influence of drink, and were bound over for 12 months in the sum of £25 to come up for judgment if called upon and ordered to pay £2 17*s.* costs."

Dr. Gray appeared. Mr. Harper read testimonials on his behalf, and the respondent gave assurances of his intention never again to offend in the same manner. The Council decided not to erase his name.

The Case of George Francis Donaldson Perrott, registered as of 46, Belsize-road, Uxbridge, Middlesex, M.R.C.S. Eng. 1928, L.R.C.P. Lond 1928, who had been summoned to appear before the Council on the following charge:—

> "That you were convicted of the following misdemeanours—viz.: (1) On June 16th, 1930, at the Westminster Police Court, of being drunk while in charge of a motor-car, and were fined £25 and £6 6*s.* costs, eight weeks' imprisonment in default, and your licence endorsed and forfeited for 12 months; and (2) On March 7th, 1931, at the Bournemouth Police Court, of being under the influence of drink to such an extent as to be incapable of having proper control of a motor-car of which you were the driver, and were fined £30 and £1 16*s.* 6*d.* witness fees, or three months' imprisonment in default, and were disqualified for holding a licence for 12 months."

Dr. Perrott appeared but was not represented.

Mr. Harper read testimonials written by medical men on his behalf, in one of which it was suggested that his probation should be extended for a year.

Dr. Perrott said his appointment at his hospital ended in June. It would be very difficult to get testimonials if he was moving about, and another year's probation would debar him from taking a practice. The Council decided not to erase his name from the Register.

New Penal Cases.

A CONVICTION FOR MALPRAXIS.

The Case of Mrs. Rona Lockhart Wotherspoon, registered as of 293, Main-street, Barrhead, Renfrewshire, L.R.C.P. Edin. 1914, L.R.C.S. Edin. 1914, L.R.F.P.S. Glasg. 1914, who had been summoned to appear before the Council on the following charge:—

> "That you were convicted on Nov. 24th, 1931, at the High Court, Glasgow, of the following offence—namely, of attempting to procure abortion by using an instrument, and were sentenced to nine months' imprisonment."

The respondent did not appear. Mr. Harper informed the Council that she was still serving her sentence and that she had written to him asking for an adjournment, as she had no money to employ a legal adviser. The Council did not see fit to postpone the hearing, and directed that the respondent's name be erased.

MOTOR-CAR CHARGES.

The Case of James Francis Patrick Devlin, registered as of 163, Lees-road, Oldham, M.B., B.Ch. 1916, N.U. Irel., who appeared before the Council on the following charge:—

> "That you were convicted at the Manchester City Police Court: (1) On June 14th, 1924, of being found drunk on a public highway, and were fined 5*s.* or six days' imprisonment; and (2) On Dec. 14th, 1931, of being in charge of a motor-car on a public road while under the influence of drink, and were fined £15 and ordered to pay 31*s.* 6*d.* extra costs or 49 days' imprisonment and your licence endorsed."

Mr. Harper read testimonials on Dr. Devlin's behalf, also two letters from the respondent. Dr. Devlin gave his assurance that nothing similar would occur again and the Council decided not to erase his name from the Register.

The Case of Frederick Percy Richard Gover, registered as of c/o Messrs. Gover and Co., 8, Bush-lane, Cannon-street, E.C.4, L.R.C.P. Edin. 1910, L.R.C.S. Edin. 1910, L.R.F.P.S. Glasg. 1910, who had been summoned to appear before the Council on the following charge:—

> "That you were on March 2nd, 1932, at the Mansion House Justice Room in the City of London, convicted of the following misdemeanour—namely, of driving a motor-car while under the influence of drink, and were fined £100 and 3 guineas costs and your licence suspended for three years."

Mr. Gover appeared in answer to his notice and was represented by Mr. W. B. Frampton, instructed by Messrs. Percy Robinson and Co.

Mr. Harper laid the facts before the Council, pointing out that this was in fact Mr. Gover's fifth conviction, the first having been in 1916. Convictions had included both drunkenness and careless driving. He had served one month in the second division in 1919, and in 1920 had run down a woman in Kingsway. An inquiry had been held under the National Insurance Acts in February 1921, and respondent had then declared that he would never drive a car again.

importance that the State will in the future be compelled increasingly to claim his assistance, and that inevitably the doctor must become a full-time State servant. Because this form of evolution appears certain, and because patients are beginning to demand it of him, the doctor of the future will have to know much more about the prevention of disease.

PREVENTION OF DISEASE.

"The teaching of medicine and its practice has," said Sir George Newman, "been all too often preoccupied in a confused and unequal struggle with end-results." In the same lecture he pointed out that we must teach preventive medicine not only as a special part of the curriculum, but introduce the preventive principle and the preventive trend into the main subjects—physiology, pathology, medicine, surgery, and obstetrics. The doctor of the future will be called upon to teach his patients the laws of health much more than he does at present. Soon after qualifying I remember being sent for by a intelligent woman to attend her young child for some trifling ailment. She made this the excuse for asking me a thousand questions about the food, clothing, exercise, sleep, and care generally of this child, of which I knew nothing, because I had been taught nothing. I was glad to escape after the most distressing viva voce examination I had ever had. Surely a course in physiology ought to begin with the laws of healthy living for adults and children, and if as I suspect we do not know much about these things, is it not time that definite research were undertaken?

But if we are to prevent a diseased condition arising, we must study and observe the natural history of that disease itself. It would be as sensible to study the natural history of a lion in a cage at the Zoo as that of consumption in a hospital ward. To understand the ætiology of a disease and therefore its prevention, and to some extent also its cure, the condition must be studied in the situation where it arises—in the homes of the people. I had the good fortune or misfortune to be brought up in a sheltered middle-class home. It was only when I went on extern duty and had to attend maternity cases in their own homes, that I began to understand how the poor had to exist, and could appreciate the reason for the high infantile mortality. Except on such duty the average medical student never sees disease in its natural setting, under the conditions which in many cases tend to produce it; and students who do their midwifery in hospital never get this advantage. If the medical student is to develop into a real "doctor," that is, teacher who gives instruction on the prevention of disease, he must see sick people in their homes. In my view an essential part of the training of a medical student should be the visiting of sick people in their homes in the company of the doctor who is attending them. This part of his education should take place within the last two years of medical study and preferably at the commencement of this period.

TRAINING OF SPECIALISTS.

It is time that we as a nation got rid of that most dangerous of all fallacies that any doctor is capable of undertaking any form of medical treatment. I know that in the case of emergency each one of us may have to do work for which we have had no training and of which we know little. We have simply to do our best. But unfortunately where no emergency exists work is undertaken by doctors with neither knowledge nor experience, and at present the public has no means of knowing whether the doctor who is in attendance has had efficient training for what he undertakes or not. The Medical Acts were passed so that the public may be able to distinguish between a man who has been trained as a doctor, and one who has not, and it ought to be equally easy to distinguish those who have had special training as physicians and surgeons from those who have only taken the course of study necessary for general practitioners. I should like to see a single State examination which all should be compelled to take before engaging in any form of practice and which would qualify for service as a general practitioner; and in addition, two other State examinations to be taken later by those who desire to do so, to indicate that the individual who satisfies the examiners has had the training necessary for a physician or surgeon. Other examinations might be taken to qualify for the various specialties. In each case evidence of having taken a special course of study and obtained special clinical experience would have to be produced before taking the examination.

It is a pathetic sight to see house surgeons and dressers who are going into general practice trying to learn the elements of minor surgery in a ward filled with gastrectomies and œsophagectomies, or to see a house physician and his clerks trying to become acquainted with the diagnosis and treatment of common ailments in a ward filled by diabetics, exophthalmics, and sufferers from rare diseases. And yet these very wards would be ideal for the training of those desirous of specialising as surgeons and physicians. The future general practitioner does not need to learn the details of complicated and difficult operations, and the treatment of rare medical affections. It would be nice of course if he knew all about such things, but there is so much that he must know about every-day conditions that he will spend his time to much greater advantage in the study of these.

But to whatever extent specialisation may develop in the future the diagnosis of disease must always remain largely in the hands of the general practitioner, and on his skill in the early recognition of diseased conditions the health of his patients will largely depend. Hence in the training of the general practitioner three sections of the subject of medicine will need to be especially stressed: *pathology*, because it is the basis of all scientific medicine; *diagnosis*, because the general practitioners must always form the first line of defence in the fight with disease; *prevention*, because it will be the duty of the practitioner of the future to keep his patients in good health as well as to treat them when unwell. It seems to me also that great care must be taken not to make the curriculum for the general practitioner's degree too extensive. The subject of medicine is so vast and no part of it is unimportant. While it is difficult to decide what can be safely left out it must be remembered that the average student can only absorb a certain amount of knowledge in five years, and that it is better to know a little well than a lot imperfectly. I would therefore make the curriculum limited and the standard high. A pass mark of 40 per cent. may be very nice for the student, but a patient needs more than 40 per cent. of correct diagnosis when he is ill.

A HOSPITAL MEMORIAL WING.—Last week Lady Maurice Fitzgerald opened a wing in Wexford County Hospital which has been provided by the Wexford Hunt Committee as a memorial to her daughter, Mrs. Lakin, who died from injuries sustained in the hunting field. The wing is intended for maternity patients, and a portion has been set aside for free treatment.

1931, an article advocating the use of the said alleged emedy without divulging your said interest therein. (5) By eeking by means of the said articles and circular and by a letter to Messrs. John Bell and Croyden, dated Nov. 11th, 1931, to induce registered medical practitioners to use in the reatment of their patients and to make themselves responsible for a medicament—namely, the said alleged remedy, of whose properties and/or action such practitioners were not fully informed. (6) By alleging in the said article in the *Medical World* that one of the cases therein mentioned was cured by means of the said alleged remedy, whereas he cure was in fact and to your knowledge effected by means of another and different remedy. And that in elation to the facts so alleged you have been guilty of nfamous conduct in a professional respect."

The hearing of this case took three days.

Mr. Nesfield appeared in answer to his notice, accompanied by Lord Erleigh, K.C., assisted by Mr. Arthur Ward, Counsel, instructed by Messrs. Bulcraig and Davis, Solicitors. Dr. William G. Macdonald appeared and was accompanied by Mr. Valentine Holmes, Counsel, instructed by Messrs. Bristows, Cooke, and Carpmael, Solicitors.
